Extracranial Carotid Angioplasty/Stenting

Policy Number: 7.01.68  Last Review: 6/2014

Policy
Blue Cross and Blue Shield of Kansas City (Blue KC) will provide coverage for extracranial carotid angioplasty with or without stenting when it is determined to be medically necessary because the criteria shown below are met.

When Policy Topic is covered
Carotid angioplasty with associated stenting and embolic protection may be considered medically necessary in patients with:
- 50%–99% stenosis (NASCET measurement); AND
- symptoms of focal cerebral ischemia (transient ischemic attack or monocular blindness) in previous 120 days, symptom duration less than 24 hours, or nondisabling stroke; AND
- anatomic contraindication for carotid endarterectomy (such as prior radiation treatment or neck surgery, lesions surgically inaccessible, spinal immobility, or tracheostomy).

When Policy Topic is not covered
Carotid angioplasty with or without associated stenting and embolic protection is considered investigational for all other indications including but not limited to, patients with carotid stenosis who are suitable candidates for CEA and patients with carotid artery dissection.

Considerations
Symptoms of carotid artery stenosis include:
- carotid transient ischemic attack (distinct focal neurological dysfunction persisting less than 24 hours),
- focal cerebral ischemia producing a nondisabling stroke (modified Rankin scale < 3 with symptoms for 24 hours or more),
- and transient monocular blindness (amaurosis fugax). Patients who have had a disabling stroke (modified Rankin scale > 3) shall be excluded from coverage.

Patients at high risk for CEA are defined as having significant comorbidities and/or anatomic risk factors (i.e., recurrent stenosis and/or previous radical neck dissection), and would be poor candidates for CEA. Significant comorbid conditions include but are not limited to:
- Age >80;
- Recent (< 30 days) Myocardial Infarction (MI);
- Left Ventricle Ejection Fraction (LVEF) < 30 percent;
- Contralateral carotid occlusion;
- New York Heart Association (NYHA) Class III or IV congestive heart failure;
- Unstable angina: Canadian Cardiovascular Society (CCS) Class III/IV;
- Renal failure: end stage renal disease on dialysis;
- Common Carotid Artery (CCA) lesion(s) below clavicle;
- Severe chronic lung disease;
- Previous neck radiation;
- High cervical Internal Carotid Artery (ICA) lesion(s);
- Restenosis of prior carotid endarterectomy (CEA);
- Tracheostomy;
- Contralateral laryngeal nerve palsy.

**Description of Procedure or Service**

Carotid artery angioplasty with stenting (CAS) is a treatment for carotid stenosis that is intended to prevent future stroke. It is an alternative to medical therapy and a less-invasive alternative to carotid endarterectomy (CEA).

**Background**

Combined with optimal medical management, carotid angioplasty with or without stenting has been evaluated as an alternative to carotid endarterectomy (CEA). Carotid angioplasty and stenting (CAS) involves the introduction of coaxial systems of catheters, microcatheters, balloons, and other devices through the femoral artery, but a transcervical approach can also be used to avoid traversing the aortic arch. The procedure typically takes 20–40 minutes. Interventionalists almost uniformly use an embolic protection device (EPD) designed to reduce the risk of stroke caused by thromboembolic material dislodged during CAS. Embolic protection devices can be deployed proximally (with flow reversal) or distally (using a filter). Carotid angioplasty rarely is performed without stent placement.

Proposed advantages of CAS over CEA include:
- General anesthesia is not used (although CEA can be performed under local/regional anesthesia)
- Cranial nerve palsies are infrequent sequelae (although almost all following CEA resolve over time)
- Simultaneous procedures may be performed on the coronary and carotid arteries

The U.S. Food and Drug Administration (FDA) has approved carotid artery stents and EPDs from various manufacturers. Examples include:
- Acculink™ and RX Acculink carotid stents and Accunet™ and RX Accunet cerebral protection filters, Guidant Corp. (approved August 2004);
- Xact RX carotid stent system and Emboshield embolic protection system, Abbott Vascular Devices (approved September 2005);
- Precise® nitinol carotid stent system and AngioGuard XP and RX emboli capture guidewire systems, Cordis Corp. (approved September 2006);
- NexStent® carotid stent over-the-wire and monorail delivery systems, Endotex Interventional Systems; and FilterWire EZ embolic protection system, Boston Scientific Corp. (approved October 2006);
- ProtégéRx® and SpiderRx®, ev3 Inc, Arterial Evolution Technology. (approved January 2007);
- Carotid Wallstent®, Boston Scientific Corp. (approved October 2008);
- Gore® Flow Reversal System (clearance February 2009); Gore® Embolic Filter (clearance May 2011)

Each FDA-approved carotid stent is indicated for combined use with an EPD to reduce risk of stroke in patients considered to be at increased risk for periprocedural complications from CEA who are symptomatic with greater than 50% stenosis, or asymptomatic with greater than 80% stenosis—degree of stenosis being assessed by ultrasound or angiogram with computed tomography (CT) angiography also sometimes used. Patients are considered at increased risk for complications during CEA if affected by any item from a list of anatomic features and comorbid conditions included in each stent system’s Information for Prescribers.

The RX Acculink Carotid Stent System is also approved for use in conventional risk patients (not considered at increased risk for complications during CEA) with symptoms and ≥70% stenosis by ultrasound or ≥50% stenosis by angiogram, and asymptomatic patients with ≥70% stenosis by ultrasound or ≥60% stenosis by angiogram.
FDA-approved stents and EPDs differ in the deployment methods used once they reach the target lesion, with the RX (rapid exchange) devices designed for more rapid stent and filter expansion. The Precise® and AngioGuard devices were studied in a randomized, controlled trial (RCT) (the SAPPHIRE trial; see Rationale section). Other devices were approved based on uncontrolled, single-arm trials or registries and comparison to historical controls. The FDA has mandated postmarketing studies for these devices, including longer follow-up for patients already reported to the FDA and additional registry studies, primarily to compare outcomes as a function of clinician training and facility experience. Each manufacturer’s system is available in various configurations (e.g., straight or tapered) and sizes (diameters and lengths) to match the vessel lumen that will receive the stent.

**Rationale**
This policy was created in 1998 and updated periodically with literature review. The last update with literature review covers the period of January 2013 through January 2014.

**Risk/benefit Ratio of Invasive Carotid Procedures**
Endovascular carotid angioplasty and stenting (CAS) or surgical endarterectomy (CEA) for carotid artery disease trades procedure-related harms of stroke and death for the benefit of reduced stroke risk over subsequent years—the balance determines whether either intervention will result in a net clinical benefit. That balance has been scrutinized for CEA although not for CAS; accordingly results from trials of CEA must be extrapolated to CAS.

A series of landmark clinical trials from the late 1980s through the 1990s compared the benefits and harms of CEA with best medical therapies then available in symptomatic and asymptomatic individuals with carotid artery stenosis.(1-7) Those trial results defined the magnitude of risk reduction for stroke, and periprocedural stroke and death rates that can be traded to achieve a net clinical benefit or benefit outweighing harm—30-day rates less than 3% for asymptomatic (>60% stenosis), and less than 6% for symptomatic patients (50%-69% or 70%-99% stenosis). Furthermore, because periprocedural harms are immediate but benefit is accrued over time, a net clinical benefit is obtained only in those patients surviving long enough to counterbalance the immediate harms. The necessary life expectancy was defined by the trial duration needed to demonstrate benefit—2 years for symptomatic patients with 70% to 99% stenosis, 5 years for symptomatic patients with 50% to 69% stenosis, or asymptomatic patients with greater than 60% stenosis (summarized in the following table).

As an example of the fine line between benefit and harm, Arazi et al (8) performed a decision analysis of benefit for patients with asymptomatic stenosis using a base case derived from the Asymptomatic Carotid Surgery Trial (ACST) (periprocedural death/stroke rate of 1.8%).(7) Over a 5-year time horizon, CEA provided 4 days of stroke-free survival and a net harm when periprocedural death/disabling stroke rates exceeded 2.1%.

Since the landmark trials were performed, there have been considerable improvements in medical care and evidence of substantial decline in stroke rates with medical care in asymptomatic carotid disease.(9, 10) Current medical therapies including aggressive lipid lowering were inconsistently used in the landmark trials. While indirect, evidence for impact of improved medical care supports a perspective that guidelines for periprocedural death/stroke exceed those needed to obtain a net clinical benefit. Surgeons in contemporary clinical trials have also achieved CEA periprocedural death and stroke rates lower than those in pivotal trials. For example, in the Carotid Revascularization
Endarterectomy vs Stenting Trial (CREST),(11) the death/stroke rates for symptomatic patients was 3.2% and for asymptomatic patients was 1.4%. Accordingly, the benchmarks established decades ago may no longer be appropriate. A recent consensus document suggests benchmarks of 2.0% for asymptomatic and 4.0% for symptomatic individuals.(12)

Excluded from landmark CEA trials were patients with significant comorbidities such as those judged likely to cause death within 5 years that might also increase periprocedural and anesthetic risk for complications. Therefore, CAS has appeal as a treatment option for patients with potentially higher periprocedural risk due to medical or anatomic reasons (eg, medical factors include severe cardiac dysfunction, requirement for combined coronary and carotid revascularization, severe renal or pulmonary dysfunction, and other characteristics associated with increased surgical risk; anatomic factors include surgically inaccessible stenosis, prior radiation, prior neck surgery, spinal immobility, prior laryngeal nerve palsy, contralateral occlusion, prior ipsilateral CEA, restenosis after CEA).

Although general anesthetic risk is considered a potential reason to use CAS, CEA can typically be safely performed under local or regional anesthesia,(13) as confirmed in the 95-center General Anesthesia versus Local Anesthesia (GALA) trial.(14) Investigators randomized 3526 patients undergoing CEA to general or local anesthesia and found no difference in 30-day death/stroke/myocardial infarction (MI) rates according to anesthetic approach (risk ratio [RR], 0.94; 95% confidence interval [CI], 0.70 to 1.3).(14)

SAPPHIRE. The first major randomized controlled trial (RCT) of CAS versus CEA was the Stenting and Angioplasty, with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial.(15) The relevant conclusions are summarized as follows:

- SAPPHIRE included few patients with symptomatic stenosis at increased risk for periprocedural complications from CEA (n=96), which resulted in wide confidence intervals for estimated effects; differences between arms in 30-day and 1-year outcomes were not statistically significant.
- For patients with asymptomatic stenosis at increased risk for periprocedural complications from CEA, differences in 30-day outcomes also had wide confidence intervals and were not statistically significant.
- Early study closure resulted in fewer study patients than planned, which compromised the evaluation of noninferiority.
- Variance in differential complication rates for the 2 treatments across sites may have influenced results, because 5 of 34 sites contributed 64% of randomized patients, and data were unavailable for comparison.
- Direct comparative evidence was lacking for optimal medical management alone as an alternative to adding CAS with embolic protection device (EPD) or CEA for patients with increased risk of surgical complications.

Long-term follow-up of SAPPHIRE was reported at 3 years.(16-18) For asymptomatic and symptomatic patients combined, ipsilateral strokes from day 31 to 1080 days were observed in 4.4% of patients undergoing CAS and 3.6% with CEA (from digitized figure). Cumulative 3-year repeat target vessel revascularization (a proxy for restenosis) was more common after CEA, but the difference was not statistically significant (7.1% vs 3.0%; p=0.26).

SPACE. In 2006, the Stent-supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE) trial was published. This trial randomized 1200 patients within 180 days of neurologic symptoms, transient ischemic attack (TIA), or moderate (nondisabling) stroke, and with 50% or more stenosis of the ipsilateral carotid artery, to CAS (N=605) with or without EPD (73% of procedures performed without), or CEA (N=595).(19) The analysis (N=1183) failed to conclude that CAS was noninferior to CEA by a margin of 2.5% for the primary outcome of ipsilateral ischemic stroke or death by 30 days after randomization. Periprocedural (30-day) event rates were 6.8% for the CAS group and 6.3% for the CEA group. The absolute between-group difference favored CEA and was 0.5%
Editorialists (20, 21) pointed to some methodologic issues raised with SPACE, including the high rate of rejection for potential participating collaborators (approximately 25%, based on their prior outcomes records, but review criteria were not reported), and the trial did not require use of an EPD with CAS (although 30-day event rates were 7.3% with vs 6.7% without EPD).

Long-term follow-up of the SPACE study was reported at 2 years. (17) Approximate annual ipsilateral stroke rates from day 31 through longest follow-up for CAS and CEA, respectively, were 0.4% and 0.4%. These results support a conclusion that following the periprocedural period (ie, 31 days to longest follow-up), stroke risk reduction in symptomatic patients not selected for medical or anatomic comorbidities is similar with either CAS or CEA. Recurrent stenosis greater than 70% was more frequent 2 years following CAS versus CEA (10.7% vs 4.6%, respectively; p=0.001).

EVA-3S. The Endarterectomy Versus Stenting in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) trial was a noninferiority comparison of CAS (with EPD in 92%) versus CEA in symptomatic patients at average risk for complications from CEA with 60% or more stenosis of the ipsilateral carotid artery. (22) The trial was terminated prematurely (n=527 enrolled; original target: n=872), based on interim analysis of 30-day outcomes. The incidence of any stroke or death through 30 days was 3.9% (95% CI, 2.0% to 7.2%) after CEA and 9.6% (95% CI, 6.4% to 14%) after CAS (RR=2.5; 95% CI, 1.2% to 5.1%; p=0.01).

Approximate annual ipsilateral stroke rates from day 31 through longest follow-up for CAS and CEA, respectively, were 1.1% and 0.9%. These results support a conclusion that following the periprocedural period (ie, 31 days to longest follow-up), stroke risk reduction in symptomatic patients not selected for medical or anatomic comorbidities is similar with either CAS or CEA.

Editorialists (20, 21) criticized EVA-3S for recommending but not requiring, antiplatelet premedication (3 days of aspirin plus either ticlopidine or clopidogrel) and for not requiring interventionalists to be adequately experienced with the specific stent and EPDs they used to treat trial subjects. Participating interventionalists were required to have successfully completed 12 or more CAS procedures, compared with 25 or more CEAs for vascular surgeons. EVA-3S also permitted use of 5 different stents and 7 different EPDs but required only 2 prior procedures with a new device before an investigator could use that device on a patient randomized to CAS.

ICSS. The International Carotid Stenting Study (ICSS) enrolled 1713 symptomatic patients at 50 academic medical centers across Europe, Australia, New Zealand, and Canada between May 2001 and October 2008. EPDs were recommended but not required (used in 72% of procedures), and a number of different stents and EPD types were used. Based on plausible event rates, a target study sample size of 1500 was estimated able to define a between-group difference less than 3.3% in disabling stroke or death, but also a 3.0% difference in 30-day stroke, death, or MI. Only interim 30- and 120-day results were included in the initial report. From a per-protocol analysis, the 7.1% periprocedural death/stroke death rates accompanying CAS both exceed the rate established to provide a net clinical benefit and was more than twice that following CEA (3.4%). In a substudy of 231 ICSS participants, new ischemic brain lesions were approximately 3-fold more frequent following CAS, and protection devices did not appear to mitigate their occurrence. (25) While follow-up of the sample for the primary end point is ongoing, interim results are consistent with the accompanying editorialist’s conclusion that “routine stenting in symptomatic patients must now be difficult to justify…” (26)

CREST. The Carotid Revascularization Endarterectomy vs Stenting Trial (11) was conducted between December 2000 and July 2008, enrolling 2522 patients at 117 centers across the U.S. and Canada. Of 427 interventionalists who applied to participate in CREST, only 224 (52%) were ultimately
approved.(27) Inclusion was initially restricted to recently symptomatic patients; due to slow enrollment, the protocol was amended to include asymptomatic patients. A March 2004 protocol amendment excluded further enrollment of patients 80 years and older due to poor outcomes. Of the 1271 patients randomized to CAS, 65 underwent CEA and 54 neither procedure; of the 1251 patients randomized to CEA, 13 underwent CAS and 44 neither procedure. There were 20 patients excluded from 1 site due to reported data fabrication. A sample size of 2500 was targeted to detect a 46% reduction in the hazard ratio for the primary end point of any stroke, MI, or death during the periprocedural period or ipsilateral stroke within 4 years after randomization.

In the entire sample (symptomatic and asymptomatic patients), investigators reported no difference between CAS and CEA for the primary outcome of any periprocedural stroke, MI, or death or postprocedural ipsilateral stroke. Stroke was more frequent following CAS, MI after CEA. The periprocedural MI rate after CEA (2.3%) was considerably higher in CREST than any comparable trial (eg, in EVA-3S 0.8%, SPACE 0%, ICSS 0.6%). This may be attributable to a somewhat higher prevalence of coronary artery disease among participants and routine cardiac enzyme assays, but the relative difference was large. Periprocedural CAS death/stroke rates were the lowest reported in any trial. Although participating interventionalists performing CAS were highly selected, periprocedural death/stroke rates following CAS exceeded those for CEA in symptomatic patients 5.6% versus 2.4%, respectively (the lowest rate for CAS reported in any trial); in asymptomatic patients 2.6% versus 1.4%, respectively.(28) The RR for periprocedural death/stroke in the symptomatic group was 1.89 (95% CI, 1.11 to 3.21) in the asymptomatic group 1.85 (95% CI, 0.79 to 4.34). The trial had limited power to detect a difference between procedures in the asymptomatic group. In CREST, 2-year restenosis (>70%) or reocclusion rates were similar following either CEA (6.3%) or CAS (6.0%)—2-year restenosis alone 5.8% with either procedure.(29)

Interventionalists in CREST were the most carefully selected in any trial, and the lack of similar careful selection has been a critique expressed concerning the other trials.(30) However, analyses of CAS in Medicare patients between 2005 and 2007 found that few CAS operators had the experience of CREST investigators.(31) Among the 11,846 procedures where operator experience was documented, 68% were performed by operators having performed fewer than 12 procedures.

**Section Summary**

These RCTs enrolled a mix of symptomatic and asymptomatic patients and employed different selection criteria for participating centers. Periprocedural stroke and death rates following CAS exceeded those after CEA. Following the early perioperative period, the subsequent rate of ipsilateral and/or TIA appears to be similar for the 2 procedures. While some trials found higher restenosis rates after CAS (SAPPHIRE, SPACE, EVA-3S), restenosis in CREST occurred with similar frequency following either procedure. The rates of early complications in SPACE, EVA-3S, and ICSS exceeded 6.0%. In CREST, periprocedural death/stroke rates with CAS were lower than 6% in symptomatic and 3% in asymptomatic patients. Interventionalists in CREST were the most carefully selected in any trial, and the criteria used to credential in other trials has been a focus of criticisms, along with the inconsistent use of embolic protection devices.(32)

There are no RCTs of CAS versus medical therapy. Since the pivotal CEA versus medical therapy trials, there have been marked improvements in medical therapy and declining stroke rates in asymptomatic patients with carotid stenosis. In 1993, the Asymptomatic Carotid Artery Stenosis trial(33) reported that the annual ipsilateral stroke rate was approximately 2.0% with medical therapy.(10) A recent estimate in 2009(9) described a contemporary annual ipsilateral stroke or (TIA rate of 0.34% among asymptomatic patients with asymptomatic carotid stenosis of 50% or more. A current meta-analysis of studies completing enrollment between 2000 and 2010 found a pooled estimate for annual ipsilateral stroke incidence of 1.13%. This decrease in stroke risk can be used to argue that medical therapy in asymptomatic patients is preferable to intervention.(26,34,35) Therefore, it is not possible to determine whether CAS is superior to medical therapy.
Systematic Reviews and Meta-Analysis of RCTs

Several TEC Assessments and meta-analyses have been published with similar findings. (36-40) In average risk symptomatic patients, the body of evidence demonstrates worse periprocedural outcomes with CAS compared with CEA. While data show secular improvement in periprocedural outcomes following CAS, (28, 41) there is evidence of a net harm compared with CEA. The individual patient data meta-analysis of SPACE, EVA-3S, and ICSS indicates some uncertainty in comparative periprocedural death/stroke rates for younger symptomatic patients. (42) Still, that subgroup result must be considered carefully given the larger body of evidence, lack of stratified randomization, as well as the evidence on restenosis. Meta-analyses have generally found that restenosis is more common following CAS than CEA. In a meta-analysis of 13 trials, among those reporting restenosis rates, Bangalore et al (43) reported pooled relative odds for restenosis following CAS compared with CEA of 2.8 (95% CI, 2.0 to 4.0; $I^2=0\%$).

Of note was the individual patient data meta-analysis (n=3433) of SPACE, EVA-3S and ICSS. (42) In these symptomatic patients, the 30-day death/stroke risk (per-protocol analyses) with CAS was 7.7% versus 4.4% following CEA (RR=1.74; 95% CI, 1.32 to 2.30). However, in the subgroup younger than 70 years of age, comparative 30-day death/stroke rates were 5.1% (CAS) and 4.5% (CEA) (RR=1.11; 95% CI, 0.73 to 1.71); for patients 70 years or older, 10.5% (CAS) and 4.4% (CEA) (RR=2.41; 95% CI, 1.65 to 3.51). However, randomization was not stratified by age in these trials.

Section Summary

The systematic reviews corroborate the results of individual RCTs in reporting that early adverse events are higher with CAS compared with CEA, that long-term stroke rates following the perioperative period are similar, and that restenosis is higher with CAS. These data indicate that for the average risk patient with carotid stenosis, CAS is associated with a net harm compared with CEA.

Periprocedural Death/Stroke Rates Following CAS

This question was assessed in the October 2009 TEC Assessment. (44) Noting again that CAS (like CEA) trades procedure-related risk of stroke and death for a reduced risk of stroke over subsequent years, and limits for periprocedural stroke and death rates that can be traded to achieve a net clinical benefit outlined in current guidelines are less than 3% for asymptomatic and less than 6% for symptomatic patients, the Assessment sought evidence to address the following questions:

1. Is the periprocedural death/stroke rate with CAS less than 3% for asymptomatic and less than 6% for symptomatic patients?

Eighteen multicenter prospective registries collectively enrolling 20,194 patients were identified; 11 enrolled patients in accordance with U.S. Food and Drug Administration (FDA) labeling and with 30-day outcomes available for analysis according to symptomatic status (13,783 asymptomatic and 3353 symptomatic). For 9 registries, 30-day death/stroke rates were either reported or obtained from investigators; in the remaining 2, death/stroke rates were estimated from 30-day death/stroke/MI and MI rates. An independent assessment of neurologic outcomes was required in all but 1 registry. For asymptomatic patients, the pooled periprocedural death/stroke rate was 3.9% (95% CI, 3.3% to 4.4%; $I^2=57\%$); for symptomatic patients 7.4% (95% CI, 6.0% to 9.0%; $I^2=59\%$).

A subsequent systematic review, without consideration to FDA labeling, reported results consistent with the TEC Assessment (pooled periprocedural death/stroke rates in asymptomatic patients of 3.3% [95% CI, 2.6% to 4.1%; 23 studies; 8504 patients] and in symptomatic patients of 7.6% [95% CI, 6.3% to 9.1%; 42 studies; 4910 patients]). (41)
2. For those subgroups defined by (a) medical comorbidities or (b) unfavorable anatomy, are periprocedural death/stroke rates with CAS less than 3% for asymptomatic and less than 6% for symptomatic patients?

Combined data from 2 registries reported periprocedural death/stroke rates for patients with unfavorable anatomy (45, 46) but included only 371 asymptomatic (30-day death/stroke rate, 2.7%; 95% CI, 1.5% to 4.9%) and 60 symptomatic patients (30-day death/stroke rate, 1.7%; 95% CI, 0.3% to 8.9%). No other registry reported results by symptomatic status for those subgroups.

Carotid Dissection

Carotid dissection is uncommon (incidence approximately 2 per 100,000/year) and occurs generally in younger individuals. (47) With a frequently favorable prognosis, conservative therapy with anticoagulants to restore blood flow is typically employed while surgical intervention reserved for patients whose symptoms fail to respond to conservative care. Some have described CAS as a potential treatment in those instances (48, 49); however, there are no clinical trials comparing alternative strategies and interventions. Current guidelines (detailed below) rate CAS in for this indication as a class IIb (Level of Evidence: C) recommendation.

Ongoing Clinical Trials

There are 2 large ongoing randomized trials (ACT I, enrolling asymptomatic patients at average risk for complications from CEA was terminated).

- SPACE 2, comparing CAS, CEA, and medical therapy in asymptomatic patients (ISRCTN78592017), estimated completion date January 2015;
- ACST-2, Carotid Endarterectomy Versus Carotid Artery Stenting in Asymptomatic Patients (NCT00883402), estimated completion date January 2018.

There are no ongoing or direct comparisons of CAS versus CEA in patients at increased risk for CEA complications. (50) Particularly problematic is the lack of adequate data, from either randomized or nonrandomized studies, to separately compare outcomes of the alternatives (CAS vs CEA vs current optimal medical management) in symptomatic and asymptomatic increased-risk subgroups.

Clinical Input Received Through Physician Specialty Societies and Academic Medical Centers

In response to requests, input was received through 4 physician specialty societies (6 reviewers) and 4 academic medical centers while this policy was under review in 2009. (In addition, 1 unsolicited response from a specialty society was also received.) While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted. This clinical input strongly supported use of CAS in recently symptomatic patients where CEA cannot be performed due to anatomic reasons, although acknowledging the limited evidence pertaining to this subgroup. The lack of alternative treatments for recently symptomatic patients and the established increased risk of stroke were factors supporting this opinion.

Summary

A substantial body of randomized controlled trial (RCT) evidence compares outcomes of carotid artery angioplasty with stenting (CAS) with carotid endarterectomy (CEA) for symptomatic and asymptomatic patients with carotid stenosis. The evidence does not support use of CAS in carotid artery disease for the average risk patient, because early adverse events are higher with CAS and long-term outcomes are not better. Data from RCTs and large database studies establish that the risk of CAS exceeds the
threshold set to indicate overall benefit from the procedure. Therefore, for patients with carotid stenosis who are suitable candidates for CEA, CAS is considered investigational.

However, based on limited data, clinical input, an indirect chain of evidence, and unmet medical need, CAS may be considered a reasonable treatment option in recently symptomatic patients when CEA cannot be performed due to anatomic reasons. For this population, CAS may be considered medically necessary. It is considered investigational for all other indications, including carotid dissection.

</table>
Except in extraordinary circumstances, carotid revascularization by either CEA or CAS is not recommended when atherosclerosis narrows the lumen by less than 50%.

Carotid revascularization is not recommended for patients with chronic total occlusion of the targeted carotid artery.

Carotid revascularization is not recommended for patients with severe disability caused by cerebral infarction that precludes preservation of useful function.

Levels of evidence: A (data derived from multiple randomized controlled trials or meta-analyses; multiple populations evaluated); B (data derived from a single randomized controlled trial or nonrandomized studies; limited populations evaluated); C (only consensus opinion of experts, case studies, or standard of care; very limited populations evaluated).

Class IIb "May be considered"

In symptomatic patients requiring carotid revascularization, CAS may be considered as an alternative to CEA in high-volume centers with documented death or stroke rate <6%

Levels of evidence: A (data derived from multiple randomized clinical trials or meta-analyses); B (data derived from a single randomized clinical trial or large nonrandomized studies); C (consensus of opinion of the experts and/or small studies, retrospective studies, registries).

NICE(56)

“Current evidence on the safety of CAS placement for asymptomatic extracranial carotid stenosis shows well documented risks, in particular, the risk of stroke. The evidence on efficacy is inadequate in quantity. Therefore, this procedure should only be used with special arrangements for clinical governance, consent, and audit or research.”

Australasian(57)

“CAS may be considered as a treatment option for patients with symptomatic severe carotid stenosis who are at high risk of stroke, but are surgically unsuitable for CEA, namely postradiation therapy, block dissection of the neck, in situ tracheostomy, recurrent stenosis following previous CEA, severe cervical spine arthritis, surgically inaccessible carotid stenosis (e.g., obesity, high carotid bifurcation), contralateral recurrent laryngeal nerve injury, and contralateral internal carotid occlusion.”

“The overall results of randomized controlled trials indicate that CAS is not as safe as CEA for treatment of symptomatic carotid stenosis for prevention of ipsilateral stroke.”

“There is currently no evidence to support CAS as a treatment for asymptomatic carotid stenosis.”

Medicare National Coverage(58)

From March 2001, Medicare’s national coverage policy restricted coverage for carotid angioplasty and stenting to patients participating in a clinical trial with category B investigational device exemption (IDE) designation from FDA. Percutaneous transluminal angioplasty (PTA) of the vertebral and cerebral arteries remained noncovered.

When FDA approved the first (Guidant) devices, Medicare coverage under the IDE trial policy was no longer available for that manufacturer’s devices and was not applicable to FDA-required postapproval studies. Thus, on October 12, 2004, Medicare broadened its national coverage policy and “determined that the evidence is adequate to conclude that percutaneous transluminal angioplasty (PTA) with carotid stent placement is reasonable and necessary when performed consistent with FDA approval of the carotid stent device and in an FDA required post-approval study.” For unapproved stents and embolic protection devices (EPDs), the prior policy remained in effect and restricted coverage to patients participating in an FDA-approved category B IDE trial of stent placement in the cervical carotid artery.

While the Medicare decision differed from the conclusions of this policy, Medicare made a public policy decision “that making available new, effective therapies aimed at addressing treatment and prevention of cerebrovascular disease was important to Medicare beneficiaries.” Medicare also noted that it recognized value in supporting postapproval studies as “the collected data may provide an opportunity for practitioners to determine which patients are most appropriate for carotid artery stenting and to reinforce IDE trial data on health outcomes and adverse events.”
CMS provides a continually updated listing of facilities eligible for Medicare reimbursement that met CMS's minimum facility standards for performing carotid artery stenting for high-risk patients.

On March 17, 2005, CMS determined that CAS with EPD is reasonable and necessary for patients at high risk for CEA who also have symptomatic carotid artery stenosis 70% or more. CMS limited coverage for these patients to procedures performed using FDA-approved devices. CMS also limited coverage for patients at high risk for CEA with symptomatic carotid artery stenosis between 50% and 70%, and for patients at high risk for CEA with asymptomatic stenosis 80% or more, to FDA-approved Category B IDE clinical trials for unapproved devices, or to FDA-required postapproval studies for approved devices. CMS defined patients at high risk for CEA as having significant comorbidities and/or anatomic risk factors (ie, recurrent stenosis and/or previous radical neck dissection) who would be poor candidates for CEA in the opinion of a surgeon. The list of CMS-certified facilities for CAS with EPDs is now available online at: https://www.cms.gov/MedicareApprovedFacilities/CASF/list.asp (Last accessed February 2013).

The paragraph below provides CMS’ reasoning for this change in coverage policy:

“Considering the evidence and clinical situation, there appears to be sufficient evidence to infer that CAS with embolic protection can improve health outcomes for patients with severe symptomatic stenosis ≥70% who are also at high risk for CEA, if performed with the same expertise and rate of adverse events as demonstrated in the published clinical trials. Since patients with severe symptomatic stenosis ≥70% are at high risk for stroke, carotid interventions to reduce the risk of stroke should be considered. Although the published studies on CAS have various potential biases, we feel that the need for an alternative treatment to CEA for patients who are truly at high risk for CEA should be factored into the coverage decision, unlike the BCBS TEC report, which did not consider this circumstance. By not covering this group, symptomatic patients who also are at high risk for surgery may be left with no other treatment options. The risk benefit consideration may be similarly influenced. However, having mentioned this situation, the high risk CAS studies compared CAS to CEA and found that CEA can be performed as well as CAS in a group classified as high risk. Therefore, two comparable options exist for patients with symptomatic stenosis ≥70% who are at high risk.”

On April 30, 2007, a decision memo reaffirmed CMS’s previous decision following a request to expand coverage while clarifying that “CAS is only covered when used with an embolic protection device and is, therefore, not covered if deployment of the distal embolic protection device is not technically possible.” On October 14, 2008, in the sixth reconsideration, and on December 9, 2009, in the seventh reconsideration, CMS reaffirmed their prior coverage decisions.

On January 25, 2012, CMS convened a MEDCAC panel to consider “Management of Carotid Atherosclerosis.” Panel members voted on specific questions using a scale of 1 (low confidence) to 5 (high confidence). For symptomatic patients not considered at high-risk, the mean scores to the question of whether CAS is the favored treatment strategy in this population was 1.85 and for CEA 3.6. For asymptomatic patients not considered high-risk the evidence was not judged to reach a level of certainty to provide allow determining a favored treatment.

including radiologic supervision and interpretation, percutaneous; initial vessel

Transcatheter placement of extracranial vertebral or intrathoracic carotid artery stent(s),
including radiologic supervision and interpretation, percutaneous; each additional vessel
(List separately in addition to code for primary procedure)

Beginning in 2014, the following new CPT code is effective:

37217: Transcatheter placement of an intravascular stent(s), intrathoracic common carotid
artery or innominate artery by retrograde treatment, via open ipsilateral cervical carotid artery
exposure, including angioplasty, when performed, and radiological supervision and
interpretation.

This code indicates the procedure is performed trancervically or by retrograde approach, but is
considered carotid stenting.
