INSTRUCTIONS FOR USE

The following Coverage Policy applies to health benefit plans administered by Cigna companies. Coverage Policies are intended to provide guidance in interpreting certain standard Cigna benefit plans. Please note, the terms of a customer's particular benefit plan document (Group Service Agreement, Evidence of Coverage, Certificate of Coverage, Summary Plan Description (SPD) or similar plan document) may differ significantly from the standard benefit plans upon which these Coverage Policies are based. For example, a customer's benefit plan document may contain a specific exclusion related to a topic addressed in a Coverage Policy. In the event of a conflict, a customer's benefit plan document always supersedes the information in the Coverage Policies. In the absence of a controlling federal or state coverage mandate, benefits are ultimately determined by the terms of the applicable benefit plan document. Coverage determinations in each specific instance require consideration of 1) the terms of the applicable benefit plan document in effect on the date of service; 2) any applicable laws/regulations; 3) any relevant collateral source materials including Coverage Policies and; 4) the specific facts of the particular situation. Coverage Policies relate exclusively to the administration of health benefit plans. Coverage Policies are not recommendations for treatment and should never be used as treatment guidelines. In certain markets, delegated vendor guidelines may be used to support medical necessity and other coverage determinations. Proprietary information of Cigna. Copyright ©2014 Cigna

Coverage Policy

Bariatric surgery is specifically excluded under many benefit plans and may be governed by state and/or federal mandates. Please refer to the applicable benefit plan document to determine benefit availability and the terms and conditions of coverage.

Unless excluded from the benefit plan, this service is covered when the following medical necessity criteria are met.

Cigna covers bariatric surgery for the treatment of morbid obesity using a covered procedure outlined below as medically necessary when ALL of the following criteria are met:

- The individual is ≥ 18 years of age or has reached full expected skeletal growth AND has evidence of EITHER of the following:
  - a BMI (Body Mass Index) ≥ 40
  - a BMI (Body Mass Index) 35–39.9 with at least one clinically significant obesity-related comorbidity, including but not limited to the following:
    - mechanical arthropathy in a weight-bearing joint
    - type 2 diabetes mellitus
    - poorly controlled hypertension (systolic blood pressure at least 140 mm Hg or diastolic blood pressure 90 mm Hg or greater, despite optimal medical management)
    - hyperlipidemia
    - coronary artery disease
- lower extremity lymphatic or venous obstruction
- obstructive sleep apnea
- pulmonary hypertension
- Medical management including evidence of active participation within the last 12 months in a weight-management program that is supervised either by a physician or a registered dietician for a minimum of three consecutive months (i.e., \( \geq 89 \) days). The weight-management program must include monthly documentation of \textbf{ALL} of the following components:
  - weight
  - current dietary program
  - physical activity (e.g., exercise program)

Programs such as Weight Watchers\textsuperscript{®}, Jenny Craig\textsuperscript{®} and Optifast\textsuperscript{®} are acceptable alternatives if done in conjunction with the supervision of a physician or registered dietician and detailed documentation of participation is available for review. However, physician-supervised programs consisting exclusively of pharmacological management are not sufficient to meet this requirement.

- A thorough multidisciplinary evaluation within the previous six months which includes \textbf{ALL} of the following:
  - an evaluation by a bariatric surgeon recommending surgical treatment, including a description of the proposed procedure(s) and all of the associated Current Procedural Terminology (CPT) codes
  - a separate medical evaluation from a physician other than the requesting surgeon that includes a recommendation for bariatric surgery
  - unequivocal clearance for bariatric surgery by a mental health provider
  - a nutritional evaluation by a physician or registered dietician

**Bariatric Surgery Procedures:**

When the specific medical necessity criteria noted above for bariatric surgery have been met, Cigna covers \textbf{ANY} of the following open or laparoscopic bariatric surgery procedures for the treatment of morbid obesity:

- Roux-en-Y gastric bypass (CPT codes 43644, 43645, 43846, 43847)
- adjustable silicone gastric banding (e.g., LAP-BAND\textsuperscript{®}, REALIZE\textsuperscript{™}) (CPT code 43770)
- biliopancreatic diversion with duodenal switch (BPD/DS) for individuals with a BMI (Body Mass Index) > 50 (CPT code 43845)
- sleeve gastrectomy (SG) (CPT code 43775)
- vertical banded gastroplasty (CPT code 43842)

Cigna covers adjustment of a silicone gastric banding as medically necessary to control the rate of weight loss and/or treat symptoms secondary to gastric restriction following a medically necessary adjustable silicone gastric banding procedure.

Cigna does not cover the following bariatric surgery procedures for the treatment of morbid obesity, because each is considered experimental, investigational or unproven (this list may not be all-inclusive):

- Roux-en-Y gastric bypass combined with simultaneous gastric banding biliopancreatic diversion (BPD) without duodenal switch (DS)
- Fobi-Pouch (limiting proximal gastric pouch)
- gastric electrical stimulation (GES) or gastric pacing
- gastroplasty (stomach stapling)
- intestinal bypass (jejunoileal bypass)
- intragastric balloon
- laparoscopic greater curvature plication
- loop gastric bypass
• mini-gastric bypass
• Natural Orifice Transluminal Endoscopic Surgery (NOTES)/endoscopic oral-assisted bariatric surgery procedures, including but not limited to the following:
  - restorative obesity surgery, endoluminal (ROSE)
  - StomaphyX™,
  - duodenojejunal bypass liner (e.g., Endobarrier™)
  - transoral gastroplasty (e.g., TOGA®)

• vagus nerve blocking
• vagus nerve stimulation

Reoperation and Repeat Bariatric Surgery:
Cigna covers surgical reversal (i.e., takedown) of bariatric surgery as medically necessary when the individual develops complications from the original surgery such as stricture or obstruction.

Cigna covers revision of a previous bariatric surgical procedure or conversion to another medically necessary procedure due to inadequate weight loss as medically necessary when ALL of the following are met:

- Coverage for bariatric surgery is available under the individual’s current health benefit plan.
- There is evidence of full compliance with the previously prescribed postoperative dietary and exercise program.
- Due to a technical failure of the original bariatric surgical procedure (e.g., pouch dilatation) documented on either upper gastrointestinal (UGI) series or esophagogastroduodenoscopy (EGD), the individual has failed to achieve adequate weight loss, which is defined as failure to lose at least 50% of excess body weight or failure to achieve body weight to within 30% of ideal body weight at least two years following the original surgery.
- The requested procedure is a regularly covered bariatric surgery (see above for specific procedures).

NOTE: Inadequate weight loss due to individual noncompliance with postoperative nutrition and exercise recommendations is not a medically necessary indication for revision or conversion surgery and is not covered by Cigna.

Cigna does not cover surgical reversal (i.e., takedown) or revision of a previous bariatric surgical procedure or conversion to another bariatric surgical procedure for ANY other indication because it is considered not medically necessary.

Bariatric Surgery for the Treatment of Type 2 Diabetes Mellitus
Cigna does not cover ANY bariatric surgical procedure when performed solely for the treatment of type 2 diabetes mellitus because it is considered experimental, investigational or unproven for this indication.

Cholecystectomy, Liver Biopsy, Herniorrhaphy, Prophylactic Vena Cava Filter Placement, or Upper Endoscopy:
Cigna covers prophylactic vena cava filter placement at the time of bariatric surgery as medically necessary for individuals who are considered to be high risk for venous thromboembolism (VTE) due to a history of ANY of the following conditions:

- deep vein thrombosis (DVT)
- hypercoagulable state
- increased right-sided heart pressures
- pulmonary embolus (PE)
Cigna does not cover ANY of the following performed in conjunction with a bariatric surgery because each is considered not medically necessary:

- cholecystectomy in the absence of signs or symptoms of gallbladder disease
- liver biopsy in the absence of signs or symptoms of liver disease (e.g., elevated liver enzymes, enlarged liver)
- herniorrhaphy for an asymptomatic hiatal hernia
- routine vena cava filter placement for individuals not at high risk for venous thromboembolism (VTE)

Cigna considers upper gastrointestinal endoscopy performed concurrent with a bariatric surgery procedure to confirm a surgical anastomosis or to establish anatomical landmarks to be an integral part of the more comprehensive surgical procedure and not separately reimbursable.

**General Background**

Obesity and overweight are defined clinically using the body mass index (BMI). BMI is an objective measurement and is currently considered the most reproducible measurement of total body fat. In adults, excess body weight (EBW) is defined as having a BMI ≥25 kg/m$^2$ (World Health Organization [WHO], 2000).

The National Heart, Lung and Blood Institute (NHLBI) (1998) defines the following classifications based on BMI. The NHLBI recommends that the BMI should be used to classify overweight and obesity and to estimate relative risk for disease compared to normal weight:

<table>
<thead>
<tr>
<th>Classification</th>
<th>BMI</th>
</tr>
</thead>
<tbody>
<tr>
<td>Underweight</td>
<td>&lt; 18.5 kg/m$^2$</td>
</tr>
<tr>
<td>Normal weight</td>
<td>18.5–24.9 kg/m$^2$</td>
</tr>
<tr>
<td>Overweight (Class 1)</td>
<td>25–29.9 kg/m$^2$</td>
</tr>
<tr>
<td>Obesity (Class 2)</td>
<td>30–34.9 kg/m$^2$</td>
</tr>
<tr>
<td>Extreme Obesity (Class 3)</td>
<td>≥ 40 kg/m$^2$</td>
</tr>
</tbody>
</table>

BMI is a direct calculation based on height and weight, regardless of gender:

$$
\text{BMI} = \frac{\text{weight (kg)}}{\text{height} \ (m^2)} \quad \text{OR} \quad \left[ \frac{\text{weight (lb)}}{\text{height (in)}^2} \right] \times 703
$$

Clinically severe or morbid obesity is defined as a BMI greater than or equal to 40 or a BMI 35–39.9 with comorbid conditions. Comorbidities of morbid obesity that may be considered include any of the following:

- mechanical arthropathy (weight-related degenerative joint disease)
- type 2 diabetes
- clinically unmanageable hypertension (systolic blood pressure at least 140 mm Hg or diastolic blood pressure 90 mm Hg or greater, or if individual is taking antihypertensive agents)
- hyperlipidemia
- coronary artery disease
- lower extremity lymphatic or venous obstruction
- severe obstructive sleep apnea
- obesity-related pulmonary hypertension
Another group of individuals who have been identified are the super-obese. Super-obesity has been defined in the literature as a BMI greater than 50.

Treatment of obesity is generally described as a two-part process:

1. assessment, including BMI measurement and risk factor identification; and
2. treatment/management

Obesity management includes primary weight loss, prevention of weight regain and the management of associated risk. During the assessment phase, the individual needs to be prepared for the comprehensive nature of the program, including realistic timelines and goals.

**Strategies for Weight Loss**

General recommendations for an overall weight-loss strategy include the following (Gorroll and Mulley, 2009):

- For overweight or obese patients not ready to lose weight, the best approach is to educate them about health risks, address other cardiovascular risk factors, and encourage the maintenance of their current weight.
- For motivated persons who are overweight (BMI 25 to 29.9 kg/m²) and have two or more obesity-related medical conditions or are frankly obese (BMI >30 kg/m²), a six-month goal of a 10% weight loss can be set (1 to 2 lb/wk) and a program of diet, exercise, and behavioral therapy prescribed. If, after six months, the target weight is not achieved, one can consider adding pharmacologic therapy for those at greatest risk (BMI >27 kg/m² plus two or more cardiovascular risk factors, or BMI >30 kg/m²).
- For markedly obese persons at greatest risk (BMI >35 kg/m² with two or more obesity-related medical conditions or BMI >40 kg/m²), consider a surgical approach if serious and repeated attempts using the foregoing measures have been unsuccessful.

The NHLBI guidelines (1998) make the following recommendations regarding nonsurgical strategies for achieving weight loss and weight maintenance:

- **Dietary Therapy:**
  - Low-calorie diets are recommended for weight loss in overweight and obese persons. Reducing fat as part of a low-calorie diet is a practical way to reduce calories.
  - Optimally, dietary therapy should last at least six months, as many studies suggest that the rate of weight loss decreases after about six months. Shorter periods of dietary therapy typically result in lesser weight reductions.
  - The literature suggests that weight-loss and weight-maintenance therapies that provide a greater frequency of contacts between the individual and the practitioner and are provided over the long term should be put in place. This can lead to more successful weight loss and weight maintenance.

- **Increased Physical Activity/Exercise** is recommended as part of a comprehensive, weight-loss therapy and weight-maintenance program because it:
  - modestly contributes to weight loss in overweight and obese adults
  - may decrease abdominal fat
  - increases cardiorespiratory fitness
  - may help with maintenance of weight loss

- **Combined Therapy:** The combination of a reduced-calorie diet and increased physical activity is recommended, since it produces weight loss, decreases abdominal fat and increases cardiorespiratory fitness.

- **Behavior Therapy:** Is a useful adjunct when incorporated into treatment for weight loss and weight maintenance.
In addition, the NHLBI recommends that weight-loss drugs approved by the U.S. Food and Drug Administration (FDA) only be used as part of a comprehensive weight-loss program, including diet and physical activity for individuals with a BMI greater than or equal to 30 with no concomitant obesity-related risk factors or diseases, or for individuals with a BMI greater than or equal to 27 with concomitant obesity-related risk factors or diseases.

Clinical supervision is an essential component of dietary management. According to the NHLBI, “frequent clinical encounters during the initial six months of weight reduction appear to facilitate reaching the goals of therapy. During the period of active weight loss, regular visits of at least once per month and preferably more often with a health professional for the purposes of reinforcement, encouragement, and monitoring will facilitate weight reduction” (NHLBI, 1998). Physicians can also provide clinical oversight and monitoring of what are often complex comorbid conditions and can select the optimal and most medically appropriate weight management, nutritional and exercise strategies. Some commercially available diet programs do not consistently provide counselors who are trained and certified as registered dieticians or with other equivalent clinical training. However, diet programs/plans, such as Weight Watchers®, Jenny Craig® or similar plans are acceptable methods of dietary management if there is concurrent documentation of at least monthly clinical encounters with a physician.

**Surgical Intervention**

The NHLBI recommends weight-loss surgery as an option for carefully-selected adult patients with clinically severe obesity (BMI of 40 or greater; or BMI of 35 or greater with serious comorbid conditions) when less-invasive methods of weight loss have failed and the patient is at high risk for obesity-associated morbidity or mortality. Surgical therapy for morbid obesity is not only effective in producing weight loss but is also effective in improving several significant complications of obesity, including diabetes, hypertension, dyslipidemia, and sleep apnea. The degree of benefit and the rates of morbidity and mortality of the various surgical procedures vary according to the procedure (Bouldin, et al., 2006).

Access to a multidisciplinary team approach, involving a physician with a special interest in obesity; a surgeon with extensive experience in bariatric procedures, a dietitian or nutritionist; and a psychologist, psychiatrist or licensed mental health care provider interested in behavior modification and eating disorders, is optimal. A mental health evaluation should specifically address any mental health or substance abuse diagnoses, the emotional readiness and ability of the patient to make and sustain lifestyle changes, and the adequacy of their support system. Realistic expectations about the degree of weight loss, the compromises required by the patient and the positive effect on associated weight-related comorbidities and quality of life should be discussed and contrasted with the potential morbidity and operative mortality of bariatric surgery.

With bariatric surgery procedures, patients lose an average of 50–60% of excess body weight and have a decrease in BMI of about 10kg/m² during the first 12–24 postoperative months. Many long-term studies show a tendency for a modest weight gain (5–7 kg) after the initial postoperative years; long-term maintenance of an overall mean weight loss of about 50% of excess body weight can be expected.

**BMI Requirement:** Selection criteria for studies have uniformly included BMI ranges for clinically severe or morbid obesity, as outlined by the NHLBI. The use of bariatric procedures in patients with lower BMI measurements, with or without comorbidities, has been evaluated primarily in case series with small patient populations with short-term follow-up. Cohen et al. (2006) reported an excess weight loss (EWL) rate of 81% for patients (n=37) with uncontrolled co-morbidities who underwent laparoscopic Roux-en-Y gastric bypass. The mean preoperative BMI for these patients was 32.5 kg/m². The follow-up range was 6─48 months. A case series (n=93) by Parikh et al. (2006) examined the effectiveness of laparoscopic adjustable gastric banding with the LAP-BAND in patients with a BMI of 30-35 kg/m². Of the 93 patients, 42 (45%) had co-morbidities, including asthma, diabetes, hypertension, and sleep apnea. At three years of follow-up, the BMI was 18-24 kg/m² in 34%, 25-29 kg/m² in 51%, and 30-35 kg/m² in 10%.

A randomized controlled trial conducted (RCT) by O’Brien et al. (2006) assigned 80 patients with mild to moderate obesity (i.e., BMI 30 kg/m² to 35 kg/m²) to a program of very-low-calorie diets, pharmacotherapy, and lifestyle change for 24 months (nonsurgical group) or to a laparoscopic adjustable gastric band placement. The surgical group was found to have significantly greater weight loss (87.2% EWL) compared to the nonsurgical group (21.8% EWL) (p<0.001) at two-year follow-up. Limitations of this RCT include small sample size, short-term follow-up, and the fact that the study was not powered for comparison of adverse events.
The International Diabetes Federation (IDF) position statement on the treatment and prevention of obesity and type 2 diabetes states that bariatric surgery is an appropriate treatment for people with type 2 diabetes and obesity (BMI ≥ 35) not achieving recommended treatment targets with medical therapies, especially where there are other obesity related co-morbidities. Under some circumstances people with a BMI 30-35 should be eligible for surgery. It is further stated that studies are needed to establish the benefit of surgery for persons with diabetes and BMI < 35 (IDF, 2011).

Some study results suggest that bariatric surgery may be effective for weight loss in obese patients (i.e., BMI 30–35), with or without comorbidities. However, larger well designed studies with long-term follow-up are needed to further define the role of bariatric procedures for this subset of individuals.

**Preoperative Weight Loss Requirement:** According to the NHLBI Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults (1998), the initial goal of weight-loss therapy should be to reduce body weight by approximately 10% from baseline. With success, further weight loss can be attempted, if indicated, through additional assessment. The NHLBI guidelines further state that:

- Bariatric surgery is not considered a first-line treatment.
- Even the most severely obese individuals (i.e., super-obese with BMI over 50) can be helped by a preoperative weight loss through a program of reduced-calorie diet and exercise therapy.
- Optimally, dietary therapy should last at least six months.
- Moderate weight loss (i.e., 10% of initial body weight) can significantly decrease the severity of obesity-associated risk factors. It can also set the stage for further weight loss, if indicated.

Bariatric surgeons and centers have advocated for preoperative weight loss, as it is believed that patients who are able to achieve this weight loss are most likely to have successful outcomes after surgery. The benefits of a preoperative weight-loss program include all of the following:

- reduction of the severity of obesity-associated risk factors, such as blood pressure, glucose intolerance, cardiorespiratory function and pulmonary function
- reduction of operative morbidity and surgical risk
- improvement in surgical access with weight loss
- identification of those individuals who will be committed to and compliant with the short-term, long-term and lifelong medical management follow-up, behavioral changes, lifestyle changes, and diet and physical exercise regimen required to ensure the long-term success of this surgery

**Literature Review:** Studies in the published peer-reviewed medical literature evaluating the impact of preoperative weight loss on the outcomes of bariatric surgery have yielded mixed results. Benotti et al. (2009) reported on 881 patients undergoing open or laparoscopic gastric bypass. All preoperative patients completed a six-month multidisciplinary program that encouraged a 10% preoperative weight loss. Study analysis demonstrated that increasing preoperative weight loss was associated with reduced complication frequencies in the entire group for total complications (p=0.004) and most likely for major complications (p=0.06).

A prospective RCT by Solomon and colleagues (2008) conducted a prospective randomized trial of patients who underwent laparoscopic Roux-en-Y gastric bypass (LRYGB) after being randomized to either the non-weight-loss group (n=35) or the weight-loss group (n=26). Patients in the weight-loss group were requested to lose 10% or more of their excess body weight prior to surgery. One-year follow-up data were available for 26 patients in the weight-loss group and 18 in the non-weight-loss group. The patients in the weight-loss group had a better weight loss profile in all categories, however there was no statistically significant difference between the two groups when patient weight, BMI, amount of excess weight-loss, change in BMI, and resolution of comorbidities were compared.

Harnisch et al (2008) performed a retrospective analysis of 1629 consecutive patients undergoing LRYGB and compared patients with a preoperative weight gain (n=115) to those with a preoperative loss (n=88) of ≥ 10 lbs. No difference was found in the % excess weight loss at 12 months. At 12 and 24 months of follow-up there was no significant difference in the resolution rates of diabetes, hypertension, and continuous positive airway pressure discontinuation. No differences in perioperative complications or conversion rates were detected.
Ali et al. (2007) reported on a series of 351 patients who had undergone LRYGB. Patients were divided into four groups depending on the percentage of body weight loss achieved before surgery: group 1, none or gain; group 2, <5%; group 3, 5-10%; and group 4, >10%. Data were collected regarding the demographics, BMI change, and excess weight loss. The maximum follow-up was 36 months. Of the 351 patients enrolled in the study, follow-up data was available for 302 at six months, 246 at 12 months, 167 at 24 months and 71 at 36 months. Groups 3 and 4 had significantly greater initial excess weight and BMI (p<0.05) but these became similar after the preoperative weight loss. Most patients (74%) were able to lose weight before surgery, with 36% losing >5% body weight. Patients who lost weight preoperatively demonstrated more excess weight loss and BMI change from baseline that reached statistical significance at several points during follow-up (p<0.05). This study is limited by its retrospective design and loss to follow-up.

Alami et al. (2007) performed a prospective randomized trial (n=61) of patients undergoing laparoscopic gastric bypass surgery. Patients were assigned preoperatively to either a weight loss group (n=26) with a 10% weight loss requirement or a group that had no weight loss requirements (n=35). The two groups were identical in terms of initial weight, BMI, and incidence of comorbidities. Perioperative complications, operative time, postoperative weight loss, and resolution of co-morbidities were analyzed. Of the 61 patients, data was available for 12 at one-year follow-up. Preoperative weight loss before LRYGB was found to be associated with a decrease in the operating room time (p=0.0084) and an improved percentage of excess weight loss in the short term (p=0.0267). Complication rates were similar in both groups. Preoperative weight loss was also not shown to have a statistically significant impact on the resolution of comorbidities. Study limitations include small sample size and loss to follow-up.

A study by Jamal et al. (2006) compared outcomes of gastric bypass patients undergoing a mandatory 13 weeks of preoperative dietary counseling (n=72) to a group of patients without this requirement (n=252). The PDC group had a higher incidence of obstructive sleep apnea compared to the no-preoperative dietary counseling group (p< 0.04). The two groups had similar incidences of obesity-related comorbidities. The dropout rate prior to surgery was reported to be 50% higher in the PDC group than in the no-preoperative dietary counseling group (p<0.05). The no-preoperative dietary counseling patients had a statistically greater percentage of excess weight loss (p<0.0001), lower BMI (p<0.015), and lower body weight (p<0.01) at one-year follow-up. Resolution of major comorbidities, complication rates, 30-day postoperative mortality, and postoperative compliance with follow-up were similar in the two groups (Jamal, et al., 2006). Limitations to this study include its lack of randomization and the relatively short-term follow-up of one year which may not have been long enough to demonstrate differences in outcomes.

A 2011 position document from the American Society for Metabolic and Bariatric Surgery (ASMBS) states that "the preoperative weight loss recommended by the surgeon and/or the multidisciplinary bariatric treatment team because of an individual patient's needs might have value for the purposes of improving surgical risk or evaluating patient adherence. However, it is supported only by low-level evidence in the published data at present" (Brethauer, 2011).

The Scottish Intercollegiate Guidelines Network (2010) evidence-based guidelines state that bariatric surgery should be considered on an individual case basis following assessment of risk/benefit in obese patients with "evidence of completion of a structured weight management program involving diet, physical activity, psychological and drug interventions, not resulting in significant and sustained improvement in the comorbidities."

According to the guidelines for bariatric surgery from the American Association of Clinical Endocrinologists (AAACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMB), all patients seeking bariatric surgery should have a comprehensive preoperative evaluation. A brief summary of personal weight loss attempts, commercial plans, and physician-supervised programs should be reviewed and documented, along with the greatest duration of weight loss and maintenance. This information is useful in substantiating that the patient has made reasonable attempts to control weight before considering obesity surgery. The guidelines state that preoperative weight loss should be considered for patients in whom reduced liver volume can improve the technical aspects of surgery (Mechanick, et al., 2008).

Despite limited evidence-based support, it is optimal for patients to demonstrate good eating and exercise habits prior to undergoing bariatric surgery in preparation for the post-surgical regimen.
Medical Clearance Recommendations: The American Association of Clinical Endocrinologists (AACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMBS) guidelines on support for the bariatric surgery patient state that all patients should undergo preoperative evaluation for obesity, related co-morbidities and causes of obesity, with special attention directed to those factors that could affect a recommendation for bariatric surgery. The preoperative evaluation must include a comprehensive medical history, psychosocial history, physical examination and appropriate laboratory testing to assess surgical risk. Patients should be followed by their primary care physician and have age and risk appropriate cancer screening before surgery. Recommended elements of medical clearance for bariatric surgery include the following (Mechanik, et al., 2013):

1. In patients considered for bariatric surgery, chest radiograph and standardized screening for obstructive sleep apnea (with confirmatory polysomnography if screening tests are positive) should be considered.
2. Tobacco use should be avoided at all times by all patients. In particular, patients who smoke cigarettes should stop, preferably at least six weeks before bariatric surgery.
3. Noninvasive cardiac testing beyond an electrocardiogram is determined on the basis of the individual risk factors and findings on history and physical examination
4. All patients should undergo evaluation of their ability to incorporate nutritional and behavioral changes before and after bariatric surgery.
5. All patients should undergo an appropriate nutritional evaluation, including micronutrient measurements, before any bariatric surgical procedure. In comparison with purely restrictive procedures, more extensive perioperative nutritional evaluations are required for malabsorptive procedures.
6. A psychosocial-behavioral evaluation, which assesses environmental, familial, and behavioral factors, should be required for all patients before bariatric surgery. Any patient considered for bariatric surgery with a known or suspected psychiatric illness, or substance abuse, or dependence, should undergo a formal mental health evaluation before performance of the surgical procedure.

Types of Bariatric Surgery
Bariatric surgery for morbid obesity involves reducing the size of the gastric reservoir, contributing to the establishment of an energy deficit by restricting caloric intake. The goal of bariatric surgery is to induce and maintain permanent loss of at least half of the preoperative, excess body weight. This amount of weight loss should bring the patient to a weight at which many or most weight-related comorbidities are reverted or markedly ameliorated. The NHLBI report (1998) has recognized two types of operations that have proven to be effective: restrictive procedures that limit gastric volume and malabsorptive procedures which in addition to limiting food intake also alter digestion.

Gastroplasty: Gastroplasty, also referred to as stomach stapling, is the prototypical restrictive procedure. A simple gastroplasty involves the stapling of the upper portion of the stomach horizontally. A small opening is left for food to pass through to the lower portion. The outlet of the pouch is restricted by a band, which slows emptying, allowing the person to feel full after only a few bites of food. It has been reported in the literature that those who have undergone this procedure seldom experience any satisfaction from eating, and tend to eat more, causing vomiting and tearing of the staple line. The available literature also reports that horizontal stapling alone has led to poor long-term weight loss. Because many simple gastroplasty patients have eventually required some type of revision operation in order to achieve successful weight loss, this procedure has largely been abandoned.

Vertical Banded Gastroplasty (VBG): This restrictive procedure uses both a band and staples to create a small stomach pouch. The pouch limits the amount of food that can be eaten at one time and slows passage of the food into the remainder of the stomach and gastrointestinal tract. VBG may be performed using an open or laparoscopic approach. Complications of VBG include esophageal reflux, leaking or rupture along the staple line, stretching of the stomach pouch from overeating.

Although reoperation rates have been reported to be higher for VBG, the available evidence in the form of RCTs, nonrandomized comparative trials, and case series (Miller, et al., 2007; Nocca, et al., 2007; Olbers, et al., 2005; Lee, et al., 2004; Morino, et al., 2003) suggests that substantial weight loss can be achieved with this restrictive procedure. VBG has been largely replaced by adjustable silicone gastric banding however, and is now rarely performed (Centers for Medicare and Medicaid Services [CMS], 2006).
**Gastric Banding:** In this restrictive procedure, a band made of special material (e.g., silicone, polypropylene mesh, Dacron vascular graft) is placed around the stomach near its upper end, creating a small pouch and a narrow passage into the larger remainder of the stomach. Adjustable gastric banding refers to bands in which the pressure can be changed without an invasive procedure. The open approach to gastric banding is considered obsolete in practice and has largely been replaced by laparoscopic techniques.

**Laparoscopic Adjustable Silicone Gastric Banding (LASGB):** LASGB is a minimally invasive gastric restrictive procedure that involves the wrapping of a saline-filled band around an area of the stomach with the goal of limiting food consumption. The adjustable band can be inflated or deflated percutaneously via an access port (reservoir) attached to the band by connection tubing, based on weight changes. The access port is placed in or on the rectus muscle, allowing for noninvasive band adjustment. This adjustment process helps determine the rate of weight loss and is an essential part of LASGB therapy. Appropriate adjustments, made up to six times annually, are critical for successful outcomes (Buchwald, 2005). Currently, adjustable gastric banding devices approved for marketing in the U.S. include the Bioenterics® LAP-BAND® Adjustable Gastric Band (LAGB®) System (INAMED Health, Santa Barbara, CA), and the REALIZE™ Adjustable Gastric Band (Ethicon Endo-Surgery, Inc., Cincinnati, OH).

**LAP-BAND:** The LAP-BAND received premarket approval (PMA) from the U.S. Food and Drug Administration (FDA) in June 2001. The FDA approval letter states that the LAP-BAND is indicated for use in weight reduction for severely obese patients with a BMI of at least 40; with a BMI of at least 35 with one or more severe comorbid conditions; or who are 100 lbs. or more over their estimated ideal weight according to the 1983 Metropolitan Life Insurance Tables. The letter further states that the device is indicated for use only in severely obese patients who have failed more conservative weight reduction alternatives, such as supervised diet, exercise and behavior modification programs (FDA, 2001).

On February 16, 2011, the FDA expanded the indication for use of the LAP-BAND to include obese individuals with a BMI of 30–35 who also have an existing condition related to their obesity. The expanded approval was based on the results of a prospective, non-randomized, multi-center five-year study (n=149) conducted under an FDA-approved Investigational Device Exemption, that examined the use of the LAP-BAND in patients with BMI measurements between 30 and 40. Of the 149 subjects, 63 had a BMI between 30 and 35. Results showed that 80% of patients demonstrated a 30% loss of excess weight which was maintained at one year. Some patients in the study lost no weight, while others lost more than 80% of their excess weight. Approximately 70% of patients experienced an adverse event, most often vomiting and difficulty swallowing. These events ranged from mild to severe; most were mild and resolved quickly. Of the 149 patients, seven required additional procedures after LAP-BAND implantation. The FDA has required that post-approval studies be performed by the manufacturer (FDA, 2011).

According to patient information provided by the manufacturer of the LAP-BAND, when the band is initially placed, it is usually left empty or only slightly inflated to allow time for adjustment to the device and healing. The first band adjustment is typically done approximately four to six weeks after the initial placement. There is no set schedule for adjustments, as the surgeon decides when it is appropriate to adjust the band based on weight loss, amount of food the individual can eat, exercise and amount of fluid currently in the band. Adjustments can be done either in the hospital or in a doctor's office. Fluoroscopy may be used to assist in locating the access port, or to guide the needle into the port. It is also used after the band has been adjusted to evaluate the pouch size and stoma size. During each adjustment, a very small amount of saline will be added to or removed from the band. The exact amount of fluid required to make the stoma the right size is unique for each person. More than one adjustment may be needed to achieve an ideal fill that will result in gradual weight loss. If a band is too loose, this may cause a patient to feel hungry or dissatisfied with small meals. A band that is too tight may result in dysphagia, regurgitation or maladaptive eating.

**REALIZE:** The REALIZE Adjustable Gastric Band received a PMA from the U.S. FDA in September 2007. Similar to the LAP-BAND, the REALIZE is indicated for weight reduction in morbidly obese patients with a BMI of at least 40 or a BMI of at least 35 combined with one or more comorbid conditions. The Band is also indicated for use only in morbidly obese adult patients who have failed more conservative weight-reduction alternatives such as supervised diet, exercise and behavior modification programs. The Band comes in one size and the fit is customized by increasing or decreasing the amount of saline in the balloon. The balloon is designed to hold up to nine milliliters of saline. Contraindications for the Band are also similar to those of the LAP-BAND and
include inflammatory diseases of the gastrointestinal tract, severe cardiopulmonary disease, portal hypertension, and cirrhosis of the liver.

**LASGB Literature Review:** Evidence in the published, peer-reviewed scientific literature suggests that laparoscopic adjustable gastric banding (LAGB) is a safe and effective surgical treatment option for patients with morbid obesity. Although a large number of studies have reported on the effectiveness of this technique, available evidence supporting the use of adjustable gastric banding is primarily in the form of retrospective and prospective case series. Numerous case series have been published, with several studies including over 500 patients each. A limited number of randomized trials have been published, with few studies comparing adjustable gastric banding with established surgical approaches, such as gastric bypass. Well-designed comparative clinical trials comparing adjustable banding with established bariatric surgical procedures are limited. BMI inclusion criteria for studies have generally been within the guidelines set forth by the NHLBI (i.e., BMI ≥ 40 or 35–39.9 with an obesity related co-morbid condition). While a number of these studies and case series report a substantial weight loss following laparoscopic banding, the percentage of EWL after one year appears to be less than the percentage of EWL associated with gastric bypass procedures (O’Brien, et al., 2003; BlueCross BlueShield Association [BCBSA], 2003). Reported success rates and results have been variable across studies.

Angrisani et al. (2007) performed a prospective, randomized comparison (n= 51) of LAGB with the LAP-BAND system and LRYGB. At five-year follow-up, the LRYGB patients had significantly lower weight and BMI and a greater percentage of excess weight loss than those in the LAGB group (p<0.001). Weight loss failure was observed in nine of 26 LAGB patients and in one of 24 LRYGB patients (p<0.001). These study results suggested that LRYGB results in a higher percentage of weight loss compared to LAGB.

Jan et al. (2005) studied a consecutive series of patients who underwent either LRYGB or LAGB over a three-year period by a single surgeon. The authors reported that the LAGB group had shorter operative times, less blood loss and shorter hospital stays as compared to the LRYGB group. The incidence of minor and major complications was reported to be similar in the two groups, with the morbidity after LRYGB potentially greater and the reoperation rate greater in the LAGB group. Early weight loss was greater in the bypass group; however, it was noted that the difference appeared to diminish over time (Jan, et al., 2005).

Several early studies reported high failure and complication rates associated with the banding procedure. Reported complications include both operative complications (splenic or esophageal injury) and late complications (band slippage, gastric erosion of the band, dilatation, reservoir deflation/leak, persistent vomiting, long-term failure to lose weight and gastric reflux) (Gustavsson, et al., 2002; Victorzon and Tolonen, 2001; Holeczy, et al., 2001).

More recent studies have reported varying rates of complications, with a focus on the more commonly occurring complications of band slippage and erosion. Rates of slippage have reportedly decreased with band improvements over time and changes in surgical technique. Himpens et al. (2011) presented long-term data from a case series of 82 patients who underwent LAGB. At 12-year follow-up, 54.3% of patients were available. Band erosion occurred in 28% of patients, with 17% of patients converting to laparoscopic Roux-en-Y gastric bypass. Overall, the mean EWL was 42.8% (range, 24%-143%) at 12 years of follow-up. A mean EWL of 48% was found for patients who still had a band in place (51.4%).

A retrospective case series (n=865) by Cherian et al. (2010) reported a 1.96% overall incidence of LAGB erosions at five years of follow-up.

Singhal et al. (2010) performed a meta-analysis (n=19 studies) of LAGB patients to examine the correlation between the occurrence rates for band erosion and slippage. The mean rates of erosion and slippage at two years or more of follow-up were found to be 1.03% and 4.93% respectively. The results demonstrated a statistically significant correlation between erosion and slippage rates (r=0.48; p=0.032).

Data supporting the use of laparoscopic gastric banding comes primarily from a large number of clinical series. There is evidence to suggest that laparoscopic adjustable gastric banding (LAGB) is safe and effective and may be a surgical option for those obese individuals with a BMI of less than 50 who are not candidates for Roux-en-Y gastric bypass (Chapman, et al., 2004). Currently there is insufficient evidence to support the use of LAGB in patients with a BMI less than 35.
Gastric Bypass: Gastric bypass procedures combine the creation of a small stomach pouch to restrict food intake and construction of a bypass of the duodenum and other segments of the small intestine to produce malabsorption. The Roux-en-Y gastric bypass (RYGB) is the most commonly performed gastric bypass procedure. RYGB has also been less frequently performed for other indications such as gastroparesis. During RYGB, a small stomach pouch is created by stapling or by vertical banding to restrict food intake. Next, a Y-shaped section of the small intestine consisting of two limbs and a common channel is attached to the pouch to allow food to bypass the duodenum and jejunum. This causes reduced calorie and nutrient absorption. The degree of intended malabsorption is determined by the length of the Roux limb or common channel and varies as follows: standard (short-limb), 40 cm; long-limb, 75 cm; and very long-limb, 150 cm. Complications of the RYGB include anastomotic leaking and strictures, nutritional deficiencies, and the dumping syndrome. The dumping syndrome occurs when a large amount of undigested food passes rapidly from the stomach into the small intestine and is characterized by abdominal pain, nausea, vomiting and weakness.

RYGB can be performed via open and laparoscopic approaches. A systematic review of the scientific literature on open and laparoscopic surgery for morbid obesity (Gentileschi, et al., 2002) concluded that laparoscopic Roux-en-Y is as safe as open RYGB. The overall body of evidence indicates that, in general, laparoscopic RYGB has been shown to achieve significant sustained weight loss with resolution of obesity-related comorbidities (Jan, et al., 2005; Schauer, et al., 2000; DeMaria, et al., 2002; Wittgrove and Clark, 2000). Evidence suggests that weight-loss outcomes are comparable to open gastric bypass at one year (BCBSA, 2003). In comparative trials, RYGB has been reported to be associated with substantially greater weight loss and reduction of comorbidities following surgery. It continues to be the surgical treatment of choice for morbid obesity (Weber, et al., 2004; BCBSA, 2003; Lee, et al., 2004).

Roux-en-Y Gastric Bypass (RYGB) Combined with Gastric Banding: The combination of RYGB with a banding procedure is being investigated as a treatment to enhance weight loss and avoid weight regain. The evidence evaluating this combined procedure is currently limited. A prospective randomized double-blind trial (n=90) by Bessler et al (2007) compared banded and nonbanded open gastric bypass for the treatment of super obesity. No significant differences were found in the overall number of complications, resolution of co-morbidities, or % excess weight loss (EWL) at six, 12, and 24 months (43.1% versus 24.7%, 64.0% versus 57.4%, and 64.2% versus 57.2%, respectively) postoperatively. The banded patients had achieved a significantly greater %EWL at 36 months (73.4% versus 57.7%; p<0.05). The incidence of intolerance to meat and bread was greater in the banded group.

The available evidence for gastric bypass combined with simultaneous gastric banding is insufficient to support safety and efficacy for the treatment of obesity, and to demonstrate a clinical benefit with improved long-term outcomes.

Loop Gastric Bypass: The loop gastric bypass involves the creation of a gastric pouch in the shape of a tube by dividing the stomach at the junction of the body and the antrum, parallel to the lesser curve. A loop of jejunum is then anastomosed to the gastric pouch. Some patients who undergo loop gastric bypass develop symptomatic bile reflux gastritis and esophagitis, necessitating conversion to RYGB (Salameh, 2006). The loop gastric bypass as developed years ago has generally been abandoned by many bariatric surgeons.

Jejunoileal Bypass: In a jejunoileal or intestinal bypass the proximal jejunum is joined to the distal ileum, bypassing a large segment of the small bowel. Various technical modifications of the jejunoileal anastomosis have been developed, all bypassing extensive length of small intestine and leading to inevitable malabsorption of protein, carbohydrate, lipids, and vitamins. However, unabsorbed fatty acids entering the colon has caused significant diarrhea in patients who have undergone this procedure. Other long-term complications have been observed in jejunoileal bypass patients, the most serious of which is irreversible hepatic cirrhosis (Collins, et al., 2007). Because of these complications, jejunoileal bypass has fallen out of favor and is no longer one of the more commonly performed bariatric procedures.

Biliopancreatic Diversion with and without Duodenal Switch: As described originally by Scopinaro, the biliopancreatic diversion (BPD) is principally a malabsorptive procedure in which the distal two-thirds of the stomach is removed. The small pouch that remains is connected directly to the final segment of the small intestine, diverting bile and pancreatic juice into the distal ileum. Increased malabsorption and greater excess weight loss (EWL) occur, but at the expense of a higher incidence of both surgical and metabolic complications.
These complications include: anastomotic ulceration, diarrhea, protein caloric malnutrition, metabolic bone disease and deficiencies in the fat-soluble vitamins, vitamin B₁₂, iron and calcium.

Hess adapted the procedure to include the duodenal switch (DS). The biliopancreatic diversion with duodenal switch (BPD/DS) incorporates both malabsorptive and restrictive mechanisms to minimize complications while still producing significant therapeutic weight loss. The procedure involves vertical subtotal gastrectomy with preservation of the pylorus. The first part of the duodenum is divided and attached to the terminal ileum. Sparing the pylorus significantly reduces the incidence of dumping syndrome, obstruction and stricture. Preservation of the early part of the duodenum results in a reduction in the incidence of vitamin and iron deficiencies. The majority of surgeons who perform BPD now incorporate DS (Neligan and Williams, 2005). In some centers, BPD/DS has been proposed as the procedure of choice for a subset of patients with a BMI > 50 or the super morbidly obese. The procedure is considered technically demanding with an operative mortality of 2% and major perioperative morbidity of 10%. Postoperative EWL is reported to range between 70% and 80%.

**BPD Literature Review:** There is limited available evidence in the literature evaluating the safety and effectiveness of BPD without DS. Gracia et al. (2007) studied two series of BPD patients depending on the length of the common and alimentary limbs in their procedures. A modified BPD (75-225 cm) was performed in 70 patients and 150 patients underwent BPD as described by Scopinaro (50-200 cm). The results were analyzed in terms of weight loss, co-morbidity improvement, and postoperative morbidity using BAROS. The follow-up range was 1-12 years. BMI loss and percentage of excess BMI lost (%EBMIL) were higher in the Scopinaro group than in the modified group, without statistical significance. At four-year follow-up, the EBMIL was 78.9% for patients in the Scopinaro group and 77.2% for those in the modified group. There was more prevalence of malnutrition and of iron deficiency in the Scopinaro group 16% and 60% respectively, than in the modified group 2% and 40% respectively. Early postoperative morbidity was 28.5% in the Scopinaro group and 15.5% in the modified group. The most common complication was wound infection 9% in the Scopinaro group versus 7% in the modified group. More major complications included wound dehiscence (n=2, 2.7%) occurring in the Scopinaro group, anastomotic leaks that required reoperation in both the Scopinaro (n=3, 2%) and the modified (n=1, 1.4%) groups. On long-term follow-up, major complications were: incisional hernia (50%, 42 %) and protein malnutrition that required in-hospital parenteral nutrition (11%, 2.8%) (n=16) respectively for patients in the Scopinaro and modified groups. Total postoperative mortality of BPD was 1.3% (3/220). The causes of death were anastomotic leak, pulmonary thromboembolism, and pneumonia with adult respiratory distress syndrome.

Guedea et al. (2004) evaluated weight loss, morbidity and mortality after BPD in 74 patients who completed five or more years of follow-up. Mean preoperative BMI was 54 +/- 8 kg/m². The procedure consisted of a 200-cm alimentary limb and a 50-cm common limb. Initial excess weight loss (EWL) and course of BMI were analyzed in terms of weight loss and co-morbidity improvement. The follow-up range was five years 70% and at seven years 71%. There were significant differences between morbidly obese and super-obese patients. EWL at one year follow-up was 67%, at two years 75%, at five years 70% and at seven years 71%. There were significant differences between morbidly obese (BMI <50 kg/m²) and super-obese (BMI >50 kg/m²), with better results in the morbidly obese group (p=0.026). There was no mortality in this series. Early postoperative morbidity was 16% with the most frequent complication being wound infection (6.75%). Major complications were: wound dehiscence (n=2, 2.7%) and anastomotic leak (2, 2.7%). The late postoperative rate of incisional hernias was 33.8%, however, 16.2% of patients had had an abdominal hernia prior to bariatric surgery. Glycemia, cholesterolemia, and triglyceridemia became normal in 100% of patients at one year after BPD and remained stable during all follow-up. Blood pressure decreased, so that 82.4% of the patients who were on antihypertensive medications had stopped these by one year after the operation. All patients who had sleep apnea syndrome and overnight continuous positive airway pressure were able to discontinue that treatment at six months.

**BPD/DS Literature Review:** Evidence evaluating the use of BPD/DS has been includes randomized controlled and comparative trials and case series. Sovik et al. (2011) conducted a randomized, parallel-group trial (n=60) comparing the outcomes of weight loss, improvements in cardiovascular risk factors, and adverse events in patients who underwent duodenal switch (n=29) versus gastric bypass (n=31). Participants were eligible for inclusion if they had a BMI of 50-60 kg/m², were 20 to 50 years of age, and had not sustained previous weight loss. Exclusion criteria were a history of major abdominal or bariatric surgery, disabling cardiopulmonary diseases, cancer, long-term treatment with oral corticosteroids, and conditions associated with poor adherence. The primary outcome was the change in BMI after two years. Secondary outcomes included anthropometric measures; concentrations of blood lipids and glucose, and adverse events. The study was completed by 58/60 patients. At two-year follow-up, there was a statistically significant difference in BMI and total cholesterol.
concentration reduction favoring duodenal switch \((p<0.001)\). Reductions in low-density lipoprotein cholesterol concentration, anthropometric measures, and fat mass were also greater after duodenal switch \((p \leq 0.010\) for each between-group comparison). Overall, significantly more participants in the duodenal switch group had adverse events occurring from surgery and up until two years: 10/31 (32\%) after gastric bypass compared to 18/29 (62\%) after duodenal switch \((p=0.021)\). It was noted that “because duodenal switch is often reserved for patients with a BMI greater than 50 kg/m\(^2\), balancing the health benefits and safety of this operation to those of other procedures is important. Study results are limited by the small sample size and relatively short-term follow-up (Sovik, et al., 2011).

Topart et al. (2011) presented five-year data from a series of 51 patients who underwent open and laparoscopic BPD-DS. Of the 51 patients, seven (7.8\%) were not available for follow-up. The five-year BMI was 31 ± 4.5 kg/m\(^2\), with a mean EWL of 71.9% ± 20.6%. Vitamin and micronutrients parameters remained stable over time, with the exception of a trend toward an increase in the parathormone levels and difficulties in maintaining a normal vitamin D level.

Søvik et al. (2010) randomized 60 patients with a BMI of 50-60 kg/m\(^2\) to undergo laparoscopic Roux-en-y gastric bypass (LRYGB) or laparoscopic BPD/DS. BMI, percentage of excess BMI lost, complications and readmissions were compared between groups. The mean BMI at one year decreased from 54.8 to 38.5 kg/m\(^2\) after LRYGB and from 55.2 to 32.5 kg/m\(^2\) after BPD/DS. The percentage of excess BMI lost was greater after BPD/DS (74.8\%) than after LRYGB (54.4\%), a difference that was statistically significant \((p<0.001)\).

O’Rourke et al. (2006) analyzed postoperative morbidity and mortality in a retrospective review of 452 patients who underwent either open or laparoscopic gastric bypass or BPD/DS. The mean BMI of all patients was 55. The overall mean follow-up time was 419 days. The mortality rate was found to be 0.9\%. Major and minor morbidity rates were reported to be 10\% and 13\%, respectively. BPD/DS was reported to be associated with higher risk of major morbidity than gastric bypass \((p=0.05)\). Anastomotic leak was analyzed separately and also occurred at a higher rate with BPD/DS than with gastric bypass. Excess weight loss was 54\% at one-year follow-up for all patients and did not differ significantly among procedure type or approach. The authors propose that older patients (i.e., ≥ 60 years) should be counseled regarding the higher risk associated with BPD/DS, as age was found to be a significant predictor of postoperative complications in this study.

In a comparative series, Prachand et al. (2006) reported on 350 super-obese patients who underwent open duodenal switch (DS) \((n=198)\) or RYGB \((n=152)\). Successful weight loss was defined as achieving at least 50\% loss of excess body weight. At 36 months, the follow-up rate was approximately 50\% for each group. The percentage excess weight loss (EWL) at this point continued to be greater for DS than RYGB, 68.9\% vs. 54.9\% respectively \((p < 0.05)\). The 30-day mortality rate was found to be equal (i.e., one of 198 for DS patients, zero of 152 for RYGB patients). The authors concluded that direct comparison of DS to RYGB demonstrates superior weight loss outcomes for DS. Limitations of the study include its nonrandomized design and loss to follow-up.

In a review of their experience with open biliopancreatic diversion with duodenal switch (BPD/DS), Hess et al. (2005) reported 10-year follow-up data on 167 (92\%) of a cohort of 182 patients. The mean initial BMI of patients was 50. 9. The average EWL was reported to be 75\%. Type 2 diabetics have had a 98\% cure rate (i.e., normal plasma glucose a few weeks after surgery). Hypercholesterolemia and other comorbidities were also reportedly improved. There were eight reversals typically due to excessive weight loss and protein malnutrition. A total of 37 revisions were necessary for the same two reasons, in addition to inadequate weight loss and uncontrolled diarrhea. The investigators maintain that BPD/DS has proven to be a safe and effective procedure for the treatment of morbid obesity with low rates of complications and sustained long-term weight loss.

Parikh et al. (2005) conducted a retrospective review of super-obese patients who underwent laparoscopic adjustable gastric banding (LAGB) \((n=192)\), RYGB \((n=97)\) or BPD with or without DS \((n=43)\). The mean BMI for these patients was 55.3. There were no mortalities. The perioperative complication rate for LAGB, RYGB and BPD was 4.7\%, 11.3\% and 16.3\%, respectively. The LAGB had a statistically significant lower complication rate compared with the other groups \((p=0.02)\). The difference in complication rate between RYGB and BPD was not statistically significant. BPD patients had the highest percentage of EWL at three-year follow-up, but these patients also had the highest complication rate. It was concluded that LAGB is the safest of the three bariatric procedures for super-obese patients.
In another retrospective review, Rabkin et al. (2003) reported results of 345 laparoscopic BPD/DS procedures for patients with a mean BMI of 50. Overall perioperative morbidity, including reoperations, was 10%. There were no deaths. The mean percentages of excess weight loss (EWL) at six, 18 and 24 months were 51%, 89% and 91%, respectively. The authors note that while the laparoscopic technique for BPD/DS is technically feasible with acceptable morbidity, there is a steep learning curve for this procedure. Also, longer-term data as well as comparison between open and laparoscopic BPD/DS patients are needed.

Anthone and colleagues (2003) conducted a review of data collected prospectively from 701 patients who underwent open BPD/DS as the primary surgical treatment of morbid obesity at a single institution. Preoperative BMI was 50 or more for 58% of patients, and 22% had a preoperative BMI of 60 or greater. There were 10 (1.4%) perioperative deaths. Significant morbidity occurred in 21 patients (2.9%). Complications included nonfatal leaks, rhabdomyolysis, wound dehiscence and bleeding requiring surgical intervention. Revisional surgery was needed in 40 patients (5.7%) due to malnutrition, persistent diarrhea or chronic, unexplained abdominal pain. EWL at one-, three- and five-year follow-up was 69% of 333 patients, 73% of 71 patients and 66% of 50 patients, respectively. At follow-up of three years (n=71) or more, patients reported and maintained a mean restriction of 63% of their preoperative intake with no specific food intolerances. Normal levels of serum albumin were reported in 98% of patients, hemoglobin in 52% and calcium in 71%. The authors noted that compared to procedures that severely restrict intake, BPD/DS allows patients to eat a wide variety of foods and approximately half of their preoperative intake without the associated dumping symptoms.

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guideline for laparoscopic bariatric surgery states that In BPD, the common channel should be 60–100 cm, and the alimentary limb 200–360 cm. DS diminishes the most severe complications of BPD, including dumping syndrome and peptic ulceration of the anastomosis. BPD is effective in all BMI >35 kg/m² subgroups, with durable weight loss and control of comorbidities beyond five years. Laparoscopic BPD provides equivalent weight loss, shorter hospital stay, and fewer complications than the open approach. BPD may result in greater weight loss and resolution of comorbidities than other bariatric surgeries, but with the highest mortality rate (SAGES, 2008).

There is insufficient evidence in the literature to support the use of BPD without DS. The available data suggests that BPD with DS is safe and technically feasible, can be accomplished in patients who are considered candidates for bariatric surgery, and can produce significant long-term weight loss. Additional well-designed randomized trials comparing BPD/DS to other procedures are needed to further define the role of open or laparoscopic BPD/DS in the treatment of morbid obesity.

**Fobi-Pouch:** The Fobi-Pouch has been proposed by one investigator as an alternative to traditional bariatric surgery. The limiting proximal gastric pouch procedure involves a small (less than 25 ml) vertical banded pouch, a Silastic® ring around the stomach creating a stoma, and a gastroenterostomy to a Roux-en-Y limb. Published evidence supporting the use of this procedure is in the form of one descriptive article (Fobi and Lee, 1998) and one case series (Fobi, et al., 2002; n=50), both authored by the developers of the technique, along with anecdotal information. Current evidence available in the published, peer-reviewed scientific literature indicates that the safety and efficacy of this procedure have not been established.

**Mini-Gastric Bypass:** The mini-gastric bypass has been proposed as a bariatric surgery method. The controversial procedure is performed laparoscopically and is similar to the Roux-en-Y technique except that, after the division of the stomach, a jejunal loop is created and anastomosed to the gastric pouch. Complications include biliary reflux and esophagitis. Evidence supporting the use of the mini-gastric bypass is in the form of small case series (Rutledge, 2001) and one small randomized open comparison of the procedure to LRYGB (Lee, et al., 2005). The authors reported similar efficacy in terms of excess weight loss (EWL) at two years. However, longer-term follow-up with regard to the risk of complications is recommended by the investigators.

There is insufficient evidence in the published, peer-reviewed scientific literature to support the safety and efficacy of the mini-gastric bypass.

**Intragastric Balloon (IGB):** Treatment with the IGB has been proposed as a temporary aid for obese patients who have had unsatisfactory results in their clinical treatment for obesity and for super-obese patients with higher surgical risk. The IGB technique allows the reduction of the gastric reservoir capacity, causing a premature sensation of satiety, facilitating the consumption of smaller amounts of food (Fernandes, et al., 2007).
The balloon is typically removed within six months of insertion. Adverse effects associated with the intragastric balloon include gastric erosion, reflux, and obstruction.

The evidence evaluating the safety and efficacy of the IGB includes RCTs and retrospective case series, some with relatively small sample sizes. In a case-control study, Genco et al. (2009) compared 40 patients who underwent LSG as a first step in BPD/DS to 80 patients who had IGB therapy and served as controls. At six-month follow-up, mean BMI was 46.2 ± 3.5 and 45.3 ± 5.5 kg/m² for the IGB and LSG patients, respectively. After 12 months IGB patients regained BMI, while LSG patients continued to lose weight. There were no significant differences between groups for the comorbidities evaluated.

A retrospective series (n=109) by Göttig et al. (2009) evaluated the clinical outcome and safety of IGB therapy in super-super-obese patients. The mean BMI was 68.8± 8.9 kg/m². After IGB, the mean percentage of excess BMI lost (%EBL) was 19.7±10.2. Improvement of comorbidities occurred in 56.8% of patients. Of the 109 patients, 69 received subsequent bariatric surgery and 10 patients received a second IGB after removal of the first due to non-significant weight and BMI loss.

Imaz et al. (2008) performed a meta-analysis of 15 studies (n=3608) on IGB for the treatment of obesity. The efficacy at balloon removal was estimated with a meta-analysis of two RCTs (n=75 patients) that compared balloon versus placebo. The estimates for weight lost at balloon removal were 14.7 kg, 12.2% of initial weight, and 5.7 kg/m², 32.1% of excess weight. These differences in weight lost between the IGB and placebo groups were 6.7 kg, 1.5% of initial weight, 3.2 kg/m², and 17.6% of excess weight. The majority of complications were reported to be mild and the early removal rate was 4.2%. In the opinion of the authors, the available evidence demonstrates that IGB is an effective treatment to lose weight in the short-term, but does not verify the maintenance of this weight loss over the long term (Imaz, et al., 2008).

In a Cochrane review of the evidence for IGB, Fernandes et al. (2007) included nine randomized, controlled clinical trials (n=395) spanning the years 1988 to 1999. One study was performed in 2005. In these trials, IGB was compared to no treatment, diet and a combination of balloon placement and diet. According to the authors, results indicated that compared with conventional management, the IGB did not show convincing evidence of a greater weight loss. Although few serious complications of intragastric balloon placement occurred, the relative risks for minor complications like gastric ulcers and erosions were significantly raised (Fernandes, et al., 2007).

A technology assessment of the IGB from the Canadian Coordinating Office for Health Technology Assessment (CCOHTA) concluded that moderate weight loss may be achieved with IGB placement if patients are compliant with a weight-reduction program. Weight gain has been found to recur when the balloon is removed after six months. More data are needed before the IGB can be compared to other short-term interventions such as low-calorie diets (CCOHTA, 2006).

A larger retrospective study conducted by Genco et al. (2005) evaluated 2515 patients with a mean BMI of 44.4 who underwent intragastric balloon placement. The balloon was removed after six months. Mortality, complications, BMI, percentage excess weight loss (EWL), BMI loss and comorbidities were evaluated. The overall complication rate was reported to be 2.8%, including the death of two patients. Gastric perforation occurred in five patients (0.19%), four of whom had undergone previous gastric surgery: A total of 19 gastric obstructions (0.76%) presented in the first week after balloon positioning and were successfully treated by balloon removal. Preoperative comorbidities resolved in 617 (44.3%) of 1394 patients. After six months, mean BMI was 35.4 and the EWL was 33.9%. BMI loss was reported to be 4.9 (range 0–25). Despite the complications noted, it was concluded that intragastric balloon is an effective procedure with reduced comorbidities and satisfactory weight loss within a follow-up period of six months. Previous gastric surgery was noted to be a contraindication to intragastric balloon placement.

Doldi et al. (2000) reported on intragastric balloon placement in 132 obese and morbidly obese patients. Mean BMI was 41.0 (29–81). The balloon was removed in the majority of patients four months after insertion. Mean weight loss was 14.4 kg, and mean reduction in BMI was 5.2. The weight loss produced an improvement of the complications associated with the obesity. Complications observed included balloon intolerance necessitating early removal from nine patients and two cases of gastric ulcer at balloon removal. The authors of this early study stated that the indications for intragastric balloon placement should be patients with a BMI > 40 in preparation for a bariatric operation; patients with BMI 30–35 with a chronic disease otherwise unresolved; patients with BMI < 30 in a multidisciplinary approach.
Currently, the available evidence in the published, peer-reviewed scientific literature is insufficient to establish the safety and efficacy of this procedure.

**Sleeve Gastrectomy (SG):** SG, also known as partial or vertical gastrectomy, is a restrictive procedure that is now being proposed as a definitive procedure for morbid obesity or as the first procedure in a staged surgical approach for those with very high BMI (BMI >60 kg/m²). Weight loss following SG is thought to reduce the risk of a subsequent, more extensive procedure, such as biliopancreatic diversion, in very high-risk patients. It has been suggested that the hormone ghrelin may play a role in the weight loss associated with SG. Although resection of the fundus may lower ghrelin levels by reducing the volume of ghrelin-producing cells, low levels of this hormone after surgery may be due to the paracrine effect of gastrointestinal hormones such as glucagon-like peptide-1 (GLP-1), GLP, ghrelin, and other hormones.

SG can be an open or laparoscopic procedure and involves the resection of the greater curvature of the stomach with the remainder resembling a tube or sleeve. The resulting decrease in stomach size inhibits distention of the stomach so that early satiety is achieved. Preservation of the pyloric sphincter prevents the dumping syndrome. Other advantages of this procedure include the lack of intestinal anastomosis and no implantation of a foreign body. Major complications associated with SG include staple-line leak and postoperative hemorrhage.

The %EWL for laparoscopic sleeve gastrectomy (LSG) has been reported to vary from 33%–90% and to be sustained up to three years. The rate of complications has ranged from 0%–29% (average 11.2%), and the mortality rate from 0–3.3%. Rates of resolution or improvement of comorbidities after SG have been found to range from 45%–95.3%. Safety and effectiveness are comparable to other established bariatric procedures, with %EWL at three years, comorbidity resolution, complication and mortality rates for RYGB being 66%, 65-84%, 9.5%, 0.56%, respectively, and for LAGB, 55%, 41-59%, 6.5%, 0.47%, respectively (Shi, et al., 2010).

A number of studies including randomized controlled trials and multiple case series have evaluated the safety and efficacy of SG. Shi et al. (2011) performed a systematic review of the literature (n=15 studies; 940 patients) analyzing outcomes of LSG compared to benchmark clinical data from LAGB and LRYGB. The %EWL for LSG varied from 33% to 90% and appeared to be sustained up to three years. The mortality rate was 0%–3.3% and major complications ranged from 0%–29% (average 12.1%). It was summarized that early, non-randomized data suggest that LSG is efficacious in the surgical management of morbid obesity. However, it is not clear if weight loss following LSG is sustainable in the long term.

ECRI issued an emerging technology report on LSG which states that for patients with morbid obesity or lesser obesity with serious comorbidity, the procedure may be performed to enable adequate weight loss and reduce comorbidities while potentially causing fewer adverse effects than bariatric surgeries that result in greater reduction of the stomach size and/or malabsorption. For patients with super obesity (BMI ≥50 kg/m²), LSG may provide a feasible and safe first step. Insufficient evidence was found to reach conclusions about the effectiveness of LSG compared to other bariatric procedures. No conclusions can be drawn regarding comparative safety because so few studies reported the same adverse events (ECRI, 2011).

Mid- to long-term results of LSG were reported in a case series (n=53) by Himpens et al. (2010). Of the 53 patients, 11 received an additional malabsorptive procedure at a later stage because of weight regain. After three years a mean EWL of 72.8% was documented, which decreased to 57.3% after six years. Analysis of a subgroup of 30 patients who received only sleeve gastrectomy demonstrated a three-year %EWL of 77.5% and six-year %EWL of 53.3%. The differences between the third and sixth postoperative year were statistically significant in both groups. In summary, after six years of follow-up the mean EWL exceeded 50% for this series of patients. However, weight regain and gastroesophageal reflux symptoms were noted to occur between the third and the sixth postoperative year.

Brethauer et al. (2009) performed a systematic review (n=36 studies) of the evidence on SG. Studies included a single nonrandomized matched cohort analysis, RCTs (n=2 studies) and uncontrolled case series (n=33 studies). The mean BMI in all 36 studies was 51.2 kg/m². The mean baseline BMI was 46.9 kg/m² for the high-risk patients (range 49.1–69.0) and 60.4 kg/m² for the primary SG patients (range 37.2–54.5). The follow-up period ranged from 3–60 months. The mean %EWL after SG reported in 24 studies was 33–85%, with an overall mean %EWL of 55.4%. The mean postoperative BMI was reported in 26 studies and decreased from a
baseline mean of 51.2 kg/m^2 to 37.1 kg/m^2 postoperatively. Improvement or remission of type 2 diabetes was found in more than 70% of patients. Significant improvements were also seen in hypertension and hyperlipidemia, as well as in sleep apnea and joint pain. The major postoperative complication rate ranged from 0%—23.8%. The most frequent complications seen were leaks (2.2%), and bleeding requiring re-operation or transfusion (1.2%). Study data for high-risk staged and primary subgroups are listed in the following table:

The authors summarized that although the long-term data are limited, based on the volume of available evidence, LSG is an effective weight loss procedure that can be performed safely as a first stage or primary procedure (Brethauer, et al., 2009).

In a prospective, randomized parallel group trial (n=27), Peterli et al. (2009) compared the effects of LRYGB to those of LSG on glycemic control in morbidly obese, mostly non-diabetic patients. After randomization, patients underwent LRYGB (n=13) and LSG (n=14). At three months of follow-up, both procedures were followed by a marked reduction in body weight and BMI (p>0.002). The LRYGB group lost 25.6 ± 9.5 kg, and the LSG group, 21.6 ± 6.0 kg, corresponding to excessive BMI losses of 43.3 ± 12.1% and 39.4 ± 9.4%, respectively (p>0.36). Both LRYGB and LSG were associated with an early and dramatic improvement in glycemic control, which was present postoperatively at one week before a significant weight loss had occurred.

An observational study (n=221) by Strain et al. (2009) reported on BMI and body composition changes after four bariatric procedures. Gastric bypass patients (n=101) were evaluated at 19.1 ± 10.6 months, BPD/DS patients (n=49) at 27.5 ± 16.3 months, adjustable gastric band (AGB) patients (n=41) at 21.4 ± 9.2 months, and sleeve gastrectomy (SG) patients (n=30) at 16.7 ± 5.6 months. The mean preoperative BMI was significantly different among the four groups (p<0.0001): 61.4 kg/m^2, 53.2, 46.7, and 44.3 kg/m^2 for the SG, BPD/DS, GB, and AGB group, respectively. The %EWL was 84%, 70%, 49%, and 38% for the BPD/DS, gastric bypass, SG, and AGB groups, respectively (p<0.0001). The AGB procedure resulted in less body fat loss within 21.5 months than SG within 16.7 months.

Arias et al (2009) performed a retrospective review of 130 consecutive patients who underwent LSG as a final procedure for morbid obesity. Patient selection criteria included patient’s preference; high risk; contraindications for gastric bypass (i.e., inflammatory bowel disease, severe small bowel adhesions); low BMI (≥35) without comorbidities; patients on anticoagulants. The mean BMI was 43.2 kg/m^2 (range 30.2-75.4). There was no mortality. Trocar site infection developed in four patients (2.8%) and one patient (0.7%) had leakage at the stapler line. The mean weight loss was 37.4 and 41.7 kg at 12 and 24 months, respectively. The mean BMI decreased to 29.5 and 27.1 at 12 and 24 months, respectively. The %EWL was 62.2 at 12 months and 67.9 at 24 months.

Fuks et al. (2009) evaluated the efficacy of laparoscopic sleeve gastrectomy (LSG) for weight loss in a series of 135 patients. The mean preoperative BMI was 48.8 kg/m^2 (range, 37-72). Median history of obesity was 17 ± 7 years. Study endpoints included mean BMI, excess weight loss, comorbidity, conversion to laparotomy, and major and minor complication rates. The median follow-up was 12.7 months. The mean postoperative BMI decreased to 39.8 kg/m^2 at six months (p<0.001). Average EWL was 38.6% and 49.4% at six months and one year, respectively. In terms of late complications, two patients had insufficient weight loss which was treated by a second-stage operation (laparoscopic duodenal switch). There was no mortality, and the major complication rate was 5.1% (n=7) due to gastric fistula in every case. BMI > 60 kg/m^2 was reported to be a risk factor for PGF.

In an RCT, Karamanakos et al. (2008) compared the effects of LRYGBP (n=16) to laparoscopic SG (n=16) on body weight, appetite, fasting, and postprandial ghrelin and peptide-YY (PYY) levels. Body weight and BMI
decreased significantly (p<0.0001) and comparably after either procedure. The %EWL was greater after LSG at six months (55.5% ± 7.6% versus 50.2% ± 6.5%; p=0.04) and 12 months (69.7% ± 14.6% versus 60.5% ± 10.7%; p=0.05). After LRYGBP fasting ghrelin levels did not change significantly compared to baseline (p=0.19), while LSG was followed by a statistically significant decrease in fasting ghrelin levels (p<0.0001). Fasting PYY levels increased after both surgical procedures (p<0.001). Appetite decreased in both groups.

Nocca et al. (2008) conducted a multicenter prospective study to evaluate the effectiveness of laparoscopic sleeve gastrectomy (LSG). The average BMI was 45.9 kg/m². Indications for the procedure included superobesity (BMI>50 kg/m²), and morbidly obese patients (BMI>40 kg/m²) or severely obese patients (BMI>35 kg/m²) with severe comorbidities (e.g., diabetes, sleep apnea, hypertension) who had high-volume eating disorders. Of the 163 patients in this study, 44 (26.99%) were superobese, 84 (51.53%) presented with morbid obesity, and 35 (21.47%) were severely obese patients. Follow-up evaluation occurred at one, six, 12, 18, and 24 months. Excess weight loss (EWL), mortality, and morbidity were analyzed. There was no operative mortality. Perioperative complications occurred in 12 cases (7.36%). The reoperation rate was 4.9% and the postoperative morbidity was 6.74% due to six gastric fistulas (3.66%). Long-term morbidity was caused by esophageal reflux symptoms (11.8%). The EWL was 48.97% at six months, 59.45% at 12 months for 120 available patients, 62.02% at 18 months, and 61.52% for the 98 patients available at 24 months of follow-up. No statistical difference was noticed in weight loss between obese and extreme obese patients. At last follow-up, 10 patients had regained weight. It was noted that long-term follow-up is needed to further evaluate the effectiveness of LSG in terms of weight regained, quality of life, and evolution of morbidities due to obesity.

Felberbauer et al. (2008) reported results for a series of 126 LSGs. After a mean follow-up of 19.1 months, patients had lost between 2.3 and 27 kg/m² or between 6.7% and 130% of their excessive weight. Within an average of 20 months, 64% of the patients lost >50% of their excess weight. Surgical complications included three cases of staple-line leakage needing revisional surgery. There were no operative mortalities. The failure rate was 6.8% with two patients who gained weight gain and four patients who achieved an EWL of <25% after one year. Study limitations include the retrospective, nonrandomized design and short-term follow-up. The authors noted that although these results are encouraging, the final place of LSG in bariatric surgery is still unclear.

Laparoscopic SG was performed in 216 obese patients and compared to adjustable Lap-Band placement, RYGB, and DS in a study by Lee et al. (2007). Of the 216 patients, five (2.3%) had a BMI > 80 kg/m², six (2.8%) had a BMI of 70-80 kg/m², and 25 (11.6%) had a BMI of 60-70 kg/m². The mean preoperative BMI was 49 ± 11 kg/m². Of the 216 patients, five (2.3%) had a BMI > 80 kg/m², six (2.8%) had a BMI of 70-80 kg/m², and 25 (11.6%) had a BMI of 60-70 kg/m². The %EWL was the greatest in the RGB and DS patients (75 ± 16% and 79 ± 12%, respectively, p=NS), least in the Lap-Band patients (47 ± 20%, p<0.01 versus RYGB and DS), and in between for the VG patients (59 ± 17%, p<0.01 versus all other groups). Complications occurred in 20 vertical gastrectomy (6.3%) patients versus 7.1% of Lap-Band patients. For the vertical gastrectomy group, leaks occurred in three (1.4%) patients, reoperations were performed in six (2.8%) patients. There were no deaths or conversions to open procedures.

Vidal et al. (2007) conducted a prospective study (n=91) comparing severely obese T2DM patients who underwent laparoscopic SG (n=39) or laparoscopic RYGB (n=52). At 12 months after surgery, subjects undergoing SG and GBP lost a similar amount of weight (%EBL: SG: 63.00 +/- 2.89%, BPG: 66.06 +/- 2.34%; p = 0.413). During that evaluation, T2DM had resolved, in 33/39 (84.6%) and 44/52 (84.6%) subjects after SG and GBP respectively (p = 0.618).

Himpens and colleagues (2006) conducted a prospective randomized study to compare the results of laparoscopic adjustable gastric banding (LAGB) and sleeve gastrectomy (SG) after one and three years of surgery. Median BMI was 37 for GB patients (n=40) versus 39 for SG patients (n=40). Weight loss, feeling of hunger, sweet eating, gastroesophageal reflux disease, complications and reoperations were assessed in both groups. Median weight loss after one year was 14 kilograms (kg) for LAGB patients and 26 kg for those who underwent SG (p<0.0001). After three years, the median weight loss for SG patients continued to be greater than for LAGB patients (p<0.0001). At three years, the median percentage EWL was 48% after LAGB and 66% after SG (p=0.0025). Loss of feeling of hunger after three years was reported in 2.9% of patients with GB and 46.7% of patients with SG (p<0.0001). Postoperative complications requiring reoperation occurred in two patients after SG. Late complications requiring reoperation affected seven patients after LAGB. It was concluded that weight loss and loss of feeling of hunger were greater for those who underwent SG. Although the number of
reoperations was found to be important in both groups, the severity of complications appears higher in SG (Himpens, et al., 2006).

Hamoui et al. (2006) presented the results of SG performed in a series of 118 patients. Median BMI was 55, with 73% of patients having a BMI ≥ 50. The procedure was performed by laparotomy in all but three cases, which were performed laparoscopically. Median hospital stay was six days. There was one perioperative death (0.85%), and 18 patients (15.3%) had postoperative complications. Median follow-up was 13 months. The median percentage EWL was 37.8% at six months, 49.4% at 12 months, and 47.3% at 24 months. According to the investigators, "Although the SG does not result in as much weight loss as the duodenal switch or gastric bypass, it can be used as a stand-alone operation or as a bridge to more complex procedures in the high-risk super-obese patient" (Hamoui, et al., 2006).

Silecchia et al. (2006) evaluated the effect of laparoscopic sleeve gastrectomy (LSG) on major comorbidities such as hypertension, type 2 diabetes and the American Society of Anesthesiologists (ASA) operative risk score in high-risk super-obese patients (n=41) undergoing two-stage laparoscopic BPD-DS. Patient selection criteria included a BMI ≥ 60 or BMI ≥ 50 with at least two severe comorbidities. In 10 patients, at least one intragastric balloon had been positioned and four had undergone laparoscopic adjustable gastric banding (LAGB), all with unsatisfactory results. At the time of surgery, 41.5% were classified as ASA 4 and 58.5% as ASA 3. Patients were evaluated every three months postoperatively and were restaged at 12 months and/or before the second procedure. The average BMI after six and 12 months was 44.5 and 40.8, respectively. After 12 months, 57.8% of the patients were free of comorbidities, and 31.5% had only one major comorbid condition. At the time of restaging, 20% of patients were still classified as ASA score 4. In the opinion of the authors, LSG represents a safe and effective procedure to achieve significant weight loss and reduction of major obesity-related comorbidities. It was also noted that the procedure reduced the operative risk (i.e., ASA score) in super-obese patients undergoing two-stage laparoscopic BPD-DS.

Cottam et al. (2006) presented 126 patients with a mean BMI of 65.3 who underwent LSG as a first-stage procedure. It was determined that 42% of these patients were ASA 3 and 52% were ASA 4. The mean number of comorbid conditions per patient was 9.3 with a median of 10 (range 3–17%). At one year after LSG, the mean EWL was 46%. A total of 36 patients with a mean BMI of 49.1 had the second-stage laparoscopic Roux-en-Y gastric bypass (LRYGB). The mean number of comorbidities in this group was 6.4, reduced from 9. The ASA class of the majority of patients had been down-staged at the time of LRYGB. The mean time interval between the first and second stages was 12.6 +/- 0.8 months. The mean and median hospital stays were 3 +/- 1.7 and 2.5 (range 2–7) days, respectively. The incidence of major complications was 8%, and no deaths were reported. It was concluded that “the staging concept of LSG followed by LRYGBP is a safe and effective surgical approach for high-risk patients seeking bariatric surgery” (Cottam, et al., 2006).

The American Society for Metabolic and Bariatric Surgery (ASMBS) updated their position statement on SG in 2009. The ASMBS “recognizes that the concept of staged bariatric surgery using lower risk procedures as the initial treatment appears to have value as a risk-reduction strategy for high-risk patients. Much of the published data supporting SG as a bariatric procedure have described favorable outcomes in patients described as high risk, making it an acceptable option for this subgroup.” In addition, a significant number of patients have demonstrated durable weight loss after SG and might not require conversion to another procedure. The ASMBS states that it is therefore justifiable to recommend SG as an ASMBS-approved bariatric procedure (ASMBS, 2009b).

According to the AACE/TOS/ASMBS guidelines, a first-stage SG may be performed in high-risk patients to induce an initial weight loss (25 to 45 kg), with the possibility of then performing a second-stage RYGB or BPD/DS after the patient’s operative risk has improved (Mechanick, et al., 2008). The 2013 update to these guidelines states that the LSG has become widely accepted as a primary bariatric operation and is no longer considered investigational (Mechanick, et al., 2013).

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guideline for laparoscopic bariatric surgery states that SG is validated as providing effective weight loss and resolution of comorbidities to 3–5 years (SAGES, 2008).

The growing volume of studies in the published peer-reviewed medical literature suggests that the safety and effectiveness rates for SG are comparable to those for other accepted bariatric procedures such as RYGB and
LAGB. There is sufficient evidence to support the use of SG as a stand-alone procedure or as the first of a two-stage procedure. Long-term data are needed to further define the role of SG for the treatment of morbid obesity.

**Laparoscopic Greater Curvature Plication**

Laparoscopic greater curvature plication, also referred to as gastric plication or gastric imbrication, is being investigated as a less invasive surgical procedure for obesity. The procedure is similar to laparoscopic sleeve gastrectomy (LSG), but does not involve removal of stomach tissue. The stomach is folded and sewn and therefore the procedure is theoretically reversible. A combination of gastric banding with greater curvature gastric plication has also been described in the literature. This procedure is similar to laparoscopic gastric plication but includes placement of the adjustable gastric band. This combined technique has been suggested to augment the early weight loss after gastric banding with possible decrease in the need for band adjustments (ASMBS, 2011).

**Literature Review**: Evidence evaluating the safety and effectiveness of laparoscopic greater curvature plication, with or without adjustable gastric banding, consists primarily of case series with patient populations ranging from 26-244 and follow-up of 12 months to five years (Niazi, et al., 2013; Fried, et al., 2012; Taha, 2012; Talebpour, et al., 2012; Skrekas, et al., 2011; Ramos, et al., 2010). Outcomes of %EWL, operative timeframes, and resolution of comorbidities have been reported. Limitations in these studies include lack of a randomized controlled design and short-term follow-up.

A systematic review (n=521 patients) by Kourkoulos et al. (2012) included prospective case series (n=8 studies) and case reports (n=2 studies). Inclusion Criteria in five studies were age over 18 years old and BMI > 40 or BMI > 35 with at least one comorbidity. Inclusion criteria were not defined in the one study with a minimum BMI of 36, as well as a second study in which minimum BMI was 30. The inclusion criteria for the remaining study included an age of 18–62 years and a BMI of 32–35 kg/m² as well as a history of GERD and obesity for more than five years with unsuccessful attempts at conservative weight-loss therapy, as this study was aimed at demonstrating the efficacy of LGCP with Nissen fundoplication in obese patients with GERD. Universal exclusion criteria included pregnancy, previous bariatric or gastric surgery, hiatal hernia, uncontrolled diabetes cardiovascular risks, a history of eating disorders, such as bulimia, medical therapy for weight loss within the previous 2 months, or any other condition that constituted a significant risk of undergoing the procedure. A BMI > 50 was defined as an exclusion criterion in two studies, or any other condition that constituted a significant risk of undergoing the procedure. A BMI > 50 was defined as an exclusion criterion in two studies. Outcomes of weight loss and complications were assessed. Reported % EWL in all studies was found to be approximately 50% at six months, 60–65% in 12 months, and 60–65% in 24 months. The total complication rate was 15.1%. The reoperation rate was 3% and the rate of conversion to another procedure was 0.2%. Mortality was zero at 24 months. The authors concluded that the literature on gastric plication and its modifications is limited. “The initial data suggests that LGCP may be effective for short- and medium-term weight loss. More data is required and randomized control trials must be completed in order to reach safe conclusions” (Kourkoulos, et al., 2012).

Another systematic review (n=307 patients) by Abdelbaki et al. (2012) also included prospective case series (n=5 studies) reviewed by Kourkoulos et al. (2012) as described above, and case reports (n=2 studies). The age range of patients was 23 to 59 years. At 12 months of follow up, excess weight loss (EWL) ranged from 23.3% to 67%. Patients were followed for more than two years in two studies with EWL rates of 57% and 65%. One study showed inadequate weight loss (<EWL 50 %), in 29/ 135 (21.48%) and failure (<EWL 30%) of weight loss in 8/135 (5.9%). Complications including gastric leaks and perforations, developed in 25/307 patients (8%), with a complication rate range of 7% to 15.3%. It was concluded that “prospective randomized studies with long-term follow-up comparing gastric plication to other well-established bariatric procedures are needed to prove the reliability and metabolic effectiveness of such new procedure” (Abdelbaki, et al., 2012).

According to the 2013 updated guidelines from the from the American Association of Clinical Endocrinologists (AACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMBS), while there are several short-term studies demonstrating relative safety and effectiveness of greater curvature plication with outcomes intermediate between LAGB and SG, more robust comparative data and conclusive data evaluating the durability of this procedure will be needed before specific recommendations can be made (Mechanick, et al., 2013).

The National Institute for Clinical Excellence (NICE) guideline indicates that while the evidence on laparoscopic gastric plication for severe obesity raises no major safety concerns in the short term, there is inadequate
evidence about safety in the long-term, specifically with regard to the reversibility of the procedure and how it affects the safety of any further gastric surgery that may be necessary (NICE, 2012).

The 2011 ASMBS policy statement on laparoscopic gastric placation explains that the quantity (n=4 studies, <300 patients) and quality (prospective or retrospective case series) of the data available at this time is insufficient to draw any definitive conclusions regarding the safety and efficacy of this procedure. The ASMBS supports the following recommendations regarding gastric plication alone or in combination with adjustable gastric band placement for the treatment of obesity (ASMBS, 2011):

1. Gastric plication procedures should be considered investigational at this time. This procedure should be performed under a study protocol with third party oversight (local or regional ethics committee, Institutional Review Board, Data Monitoring and Safety Board, or equivalent authority) to ensure continuous evaluation of patient safety and to review adverse events and outcomes.
2. Reporting of short- and long-term safety and efficacy outcomes in the medical literature and scientific meetings is strongly encouraged. Data for these procedures should also be reported to a program’s center of excellence database.
3. Any marketing or advertisement for this procedure should include a statement to the effect that this is an investigational procedure.
4. The ASMBS supports research conducted under an IRB protocol as it pertains to investigational procedures and devices. Investigator meetings held to facilitate research are necessary and supported, as is the reporting of all data through BOLD, Bariatric NSQIP or a specific research database. The ASMBS does not support CME courses on investigational procedures and devices held for bariatric surgeons for the purpose of use of investigational procedures outside an IRB research protocol.

There is insufficient evidence in the published, peer-reviewed medical literature demonstrating safety and effectiveness of gastric placation. Well-designed studies with larger patient populations comparing this technique to established bariatric procedures are needed to draw firm conclusions regarding the overall safety, efficacy and impact on health outcomes.

**Natural Orifice Transluminal Endoscopic Surgery (NOTES)**

NOTES, also referred to as endoscopic (oral)-assisted, endoluminal, or transoral incisionless surgery, involves the use of natural orifice access (e.g., mouth, anus) to perform a surgical procedure which potentially reduces or eliminates the trauma of access incisions. The NOTES technique is currently being investigated for use in a range of procedures including bariatric procedures such as gastric bypass (Schauer, et al., 2007).

**Transoral Gastroplasty (TG):** Transoral gastroplasty, also known as vertical sutured gastroplasty or endoluminal vertical, involves the use of endoscopically guided staplers that create a stapled restrictive pouch along the lesser curvature of the stomach. TOGA® system (Satiety Inc., Palo Alto, CA) developed for this procedure has not been FDA-approved. Currently there is insufficient evidence in the published peer-reviewed medical literature evaluating the safety and effectiveness of this procedure.

**Endoscopic Duodenal-jejunal Bypass Liner:** Endoscopic duodenal-jejunal bypass liner: The duodenojejunmal bypass liner (DJBL) is an endoscopically placed and removable intestinal liner. The EndoBarrier™ Gastrointestinal Liner (GI Dynamics, Lexington, MA) is described a non-surgical, physical barrier that enables food to bypass portions of the intestine. This device is proposed for bariatric preoperative weight loss but has not been approved by the FDA.

Evidence in the published peer reviewed medical literature evaluating the safety and effectiveness of the endoscopic duodenal-jejunal bypass liner is limited to few studies with small sample sizes and short-term follow-up. A 12-week sham controlled study (n=47) by Gersin et al. (2010) reported a statistically significant difference in weight loss for DJBL patients (p<0.05). However, the DJBL was explanted in 8/21 patients due to complications such as nausea, vomiting and abdominal pain.

An RCT (n=41) by Schouten et al. (2010) compared patients who received the endoscopically placed duodenal-jejunal bypass sleeve or EndoBarrier Gastrointestinal Liner (n=30), to a diet control group (n=11). Successful implantation occurred in 26 patients. Mean EWL after three months was 19.0% for device patients versus 6.9% for control patients (p<0.002). All patients had at least one adverse event, primarily abdominal pain and nausea during the first week after implantation.
According to the National Institute for Health and Care Excellence (NICE) guidance on the use of duodenal–jejunal bypass sleeves, “current evidence on the safety and efficacy of implantation of a duodenal–jejunal bypass sleeve) for managing obesity is limited in quality and quantity. Therefore, this procedure should only be used in the context of research. Well-controlled studies are needed to support the current limited evidence on weight loss in the short term” (NICE, 2013).

**Restorative Obesity Surgery, Endoluminal (ROSE):** ROSE is an endoscopic–assisted procedure that is being investigated for the treatment of weight regain following gastric bypass surgery that is caused by a gradual expansion of the gastric pouch. The stomach is accessed orally via an endoscope and the stomach pouch is reduced in size using a device such as the StomaphyX™ endoluminal fastener and delivery system (EndoGastric Solutions, Inc., Redmond, WA). StomaphyX is popularly described as a non-invasive weight loss procedure to reduce the size of a patient's stomach without any incisions.

**StomaphyX:** The StomaphyX was granted marketing approval by the FDA via the 510(k) process on March 9, 2007 because it is considered to be substantially equivalent to another device already on the market. Under the FDA 510(k) approval process, the manufacturer is not required to supply to the FDA evidence of the effectiveness of the StomaphyX prior to marketing the device. The 510(k) summary stated that the StomaphyX is substantially equivalent to LSI Solutions Flexible Suture Placement Device and the Bard Endoscope Suturing System/Bard Endocinch. According to the FDA, the StomaphyX system is indicated for use in endoluminal trans-oral tissue approximation and ligation in the gastrointestinal tract.

According to the American Society for Metabolic and Bariatric Surgery (ASMBS) there are currently a number of endoluminal innovations and novel devices and technologies in different stages of development or application to the treatment of obesity, including provisional interventions. “The theoretical goals of these therapies include decreasing the invasiveness, risk, and barriers to acceptance of effective treatment of obesity; however, these outcomes cannot be assumed and must be proven. Therefore, the use of novel technologies should be limited to clinical trials done in accordance with the ethical guidelines of the ASMBS and designed to evaluate the risk and efficacy of the intervention” (ASMBS, 2009a).

Currently there is insufficient evidence in the peer-reviewed medical literature to support the use of transluminal endoscopic surgical procedures and devices including the ROSE procedure, StomaphyX, transoral gastroplasty and the DJBL for the management of severe obesity.

There is insufficient evidence in the published, peer-reviewed scientific literature to support the use of any of the following bariatric procedures in the treatment of clinically severe/morbid obesity, as they have not been proven to achieve equivalent or improved patient outcomes relative to available alternatives:

- Fobi-Pouch
- intragastric balloon (IGB)
- mini-gastric bypass (jejunum is anastomosed to the stomach, as in the Billroth II procedure)
- Natural Orifice Transluminal Endoscopic Surgery™ (NOTES™) (e.g., ROSE, StomaphyX™)/endoscopic oral-assisted procedures

**Gastric Pacing/Gastric Electrical Stimulation (GES)**
GES is being investigated as a treatment for morbidly obese patients. It is thought that GES may cause increased satiety resulting in decreased food intake and weight loss. The exact mechanism by which gastric pacing impacts eating and behavior is unclear. There is currently insufficient evidence in the literature to support the use of GES for the treatment of obesity. Please refer to the Gastric Pacing/Gastric Electrical Stimulation (GES) Coverage Policy for additional information.

**Vagus Nerve Stimulation (VNS)**
VNS provides intermittent electrical stimulation to the tenth cranial nerve, which influences certain patterns of brain activity. The vagus nerve is a major connection between the brain and the rest of the body and as such, carries sensory information from the body to the brain and motor commands from the brain to the body. A potential use of VNS concerns the regulation of brain satiety signals. The brain knows that the stomach is empty or full, largely on the basis of information transmitted by the vagus nerve. Based on the theory the vagus signal
could be altered to modify eating behavior, VNS has been proposed as a treatment for obesity. Currently the literature regarding the use of VNS for obesity is limited and therefore conclusions about safety and efficacy cannot be made at this time. Please refer to the Vagus Nerve Stimulation (VNS) Coverage Policy for additional information.

**Vagus Nerve Blocking**

Vagus nerve blocking (VNB) or vagal blocking therapy is also being investigated as a treatment for obesity. VNB uses high-frequency, low-energy electrical pulses to block vagus nerve signals in the abdominal region, inhibiting gastric motility and increasing satiety (feeling full). No VNB devices have yet received U.S. FDA approval. Early clinical trial results suggest that VNB may achieve excess weight loss (EWL) that is comparable to approximately half of that achievable by LAGB (ECRI, 2009).

Camilleri et al. (2009) conducted an open-label multicenter study (n=31) to assess the effects of a vagal blocking device on EWL, safety, dietary intake, and vagal function. Electrodes were implanted laparoscopically near the esophagogastric junction to provide intermittent vagal blocking in patients with a BMI range of 35-50 kg/m². The mean EWL at six months follow-up was 14.2% (p<0.001). Calorie intake decreased by >30% at six months (p ≤ 0.01), with earlier satiation (p<0.001) and reduced hunger (p=0.005). There were no deaths or device-related serious adverse events. The study is limited by its small sample size and lack of randomization. Additional well-designed studies are needed to further evaluate the role of this therapy in the treatment of obesity.

Evidence evaluating the safety and effectiveness of VNB is limited at this point and is therefore insufficient to support use of the procedure for the treatment of obesity.

**Bariatric Surgery in Children and Adolescents**

Concerns have been raised about the appropriateness of bariatric surgery for children and adolescents. The impact of bariatric surgery on physical growth and sexual maturation has not been adequately explored and it is generally agreed upon that those under 18 years of age should only be considered for bariatric surgery if they have reached skeletal maturity (i.e., attained Tanner 4 or 5 pubertal development and final or near-final adult height). Physical development may be determined using hand and wrist radiographs to estimate bone age. Estimated adult height may also be determined using the mid-parental height calculation:

- **Boy**
  - In: \((\text{Father's Height} + \text{Mother's Height} + 5)/2\)
  - Cm: \((\text{Father's Height} + \text{Mother's Height} + 13)/2\)

- **Girl**
  - In: \((\text{Father's Height} - 5 + \text{Mother's Height})/2\)
  - Cm: \((\text{Father's Height} - 13 + \text{Mother's Height})/2\)

**Literature Review:** Bariatric surgery in patients under 18 years of age or in those who have not reached full expected skeletal growth has not been well-studied. A prospective RCT (n=50) by O’Brien et al. (2010) compared the outcomes of adolescents between the ages of 14 and 18 with a BMI > 35 who were assigned either to a supervised lifestyle intervention or to undergo gastric banding. In the gastric banding group 24/25 participants completed the study versus 18/25 subjects in lifestyle group. An excess weight loss of 78.8% (95% CI, 66.6%-91.0%) was reported in the gastric banding group compared to an excess weight loss of 13.2% (95% CI, 2.6%-21.0%) in the lifestyle group. At 24 months, none of the gastric banding group had the metabolic syndrome p=0.008 compared to 4/18 (22%) in the lifestyle group (P=.13). There were no perioperative adverse events. However, surgical revision was required in seven patients for either for proximal pouch dilatation or tubing injury during follow-up.

Treadwell et al. (2008) performed a systematic review and meta-analysis of the evidence on pediatric obesity and bariatric surgery. Included studies evaluated LAGB (n=8 studies; 352 patients), RYGB (n=6 studies; 131 patients), and other bariatric procedures (n=5 studies; 158 patients). The average patient age was 16.8 years (range, 9-21). Meta-analyses of BMI reductions at longest follow-up indicated sustained and clinically significant BMI reductions for both LAGB and RYGB. Comorbidity resolution was infrequently reported, but surgery appeared to resolve some conditions such as diabetes and hypertension. For LAGB, band slippage and micronutrient deficiency were the most frequently reported complications, with sporadic cases of band erosion,
port/tube dysfunction, hiatal hernia, wound infection, and pouch dilation. For RYGB, more severe complications have been documented, such as pulmonary embolism, shock, intestinal obstruction, postoperative bleeding, staple line leak, and severe malnutrition.

A case series (n=73) by Nadler et al. (2008) reported outcomes for adolescents between the ages of 13 and 17 who underwent LAGB. The mean preoperative BMI was 48. The %EWL at six-, 12- and 24-month follow-up was 35% +/- 16%, 57% +/- 23%, and 61% +/- 27%, respectively. Gastric perforation after a reoperation for band replacement occurred in one patient. Band slippage occurred in a total of six patients, and three patients developed symptomatic hiatal hernias. Two patients were lost to follow-up in the first year, and 3 patients were lost to follow-up in the second year, for an overall compliance rate of at least 89.5%.

ECRI performed an evaluation of the evidence on bariatric surgery in the pediatric population. A total of 17 studies met inclusion criteria, reporting outcomes after LAGB (n=8), RYGB (n=6), VBG (n=2), and banded bypass (n=1). The average age ranged from 15.6 years to 18.1 years, with little difference in mean age among bariatric procedures. Prior to surgery, all patients had undergone multiple unsuccessful attempts at weight loss using non-surgical methods. The report defined clinically significant weight loss as 7% of body weight. The most frequently reported complication after LAGB was band slippage. Reoperations were performed on 26 (7.92%) of the 328 LAGB patients to correct various complications. No reported in-hospital or postoperative death. The most frequently reported complication after RYGB was related to protein-calorie malnutrition and micronutrient deficiency. One postoperative death was reported for RYGB; no in-hospital death was reported. Potentially life-threatening complications such as shock, pulmonary embolism, severe malnutrition, immediate postoperative bleeding, and gastrointestinal obstructions were reported in the RYGB studies. The HTA summarized that LAGB and RYGB for morbidly obese patients aged 21 or less does lead to sustained and clinically significant weight loss and resolve comorbid conditions linked to obesity (diabetes, hypertension) compared to non-operative approaches. The evidence was found to be insufficient to allow conclusions about quantitative estimates of the precise amount of weight loss, weight loss in specific age groups (i.e., 18-21, 13-17, 12 or less), or weight loss after other bariatric surgical procedures in this population. The evidence was also found to be insufficient to permit any conclusions on potential impacts of bariatric surgery on growth and development of pediatric patients (ECRI, 2007).

Guidelines issued by the Endocrine Society Task Force recommend that bariatric surgery be considered only under the following conditions:

1. The child has attained Tanner 4 or 5 pubertal development and final or near-final adult height.
2. The child has a BMI greater than 50 kg/m² or has BMI above 40 kg/m² and significant, severe comorbidities.
3. Severe obesity and co-morbidities persist despite a formal program of lifestyle modification, with or without a trial of pharmacotherapy.
4. Psychological evaluation confirms the stability and competence of the family unit.
5. There is access to an experienced surgeon in a medical center employing a team capable of long term follow-up of the metabolic and psychosocial needs of the patient and family, and the institution is either participating in a study of the outcome of bariatric surgery or sharing data.
6. The patient demonstrates the ability to adhere to the principles of healthy dietary and activity habits.

The Task Force recommends against bariatric surgery for preadolescent children, for pregnant or breastfeeding adolescents, and for those planning to become pregnant within two years of surgery; for any patient who has not mastered the principles of healthy dietary and activity habits; for any patient with an unresolved eating disorder, untreated psychiatric disorder, or Prader-Willi syndrome (August, et al., 2008).

Recommendations from the American Academy of Pediatrics (AAP) for the treatment of overweight and obesity were issued by an expert panel of pediatricians and pediatric surgeons. According to this panel, minors being considered for bariatric surgery should “be physically mature, have a BMI of ≥ 50 kg/m² or ≥ 40 kg/m² with significant comorbidities, have experienced failure of a formal, six-month weight loss program, and be capable of adhering to the long-term lifestyle changes required after surgery. In addition, centers should offer this procedure only if surgeons are experienced in bariatric surgery and a team of specialists is capable of long-term follow-up care of the metabolic and psychosocial needs of the patient and family” (Spears, et al., 2007).
Similarly, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition states that until more data are available in children, gastric bypass surgery should be considered only for well-informed and motivated adolescents who meet the following criteria:

- severe obesity (BMI ≥ 40)
- failure of ≥ 6 months of organized attempts at weight loss
- near-complete skeletal maturity
- significant comorbidities that would be responsive to sustained weight loss

Extensive counseling, education, and support are required both before and after gastric bypass. Only a surgeon with extensive experience with bariatric surgery should perform gastric bypass surgery. Finally, adolescents undergoing gastric bypass require lifelong medical and nutritional surveillance, especially during pregnancy (Baker, et al., 2005).

Several unique concerns have been raised about bariatric surgery in pediatric populations, including questions about timing of intervention, risk-taking behaviors after successful weight loss, compliance, and durability of weight loss. These questions highlight the importance of well-designed, prospective research efforts to better inform important decisions (Daniels, et al., 2009).

The safety and efficacy of bariatric surgery have not yet been established in this population. There is insufficient evidence to support surgical intervention for morbid obesity in this subset of individuals under 18 years of age who have not reached full skeletal maturity.

Systematic Reviews on Bariatric Surgery

Cochrane Review: An updated systematic review by Colquitt et al. (2009) included RCTs (n=3) and three prospective cohort studies (n=3) comparing surgery to non-surgical management, and 20 RCTs comparing different bariatric procedures. A meta-analysis was not appropriate. It was found that surgery results in greater weight loss than conventional treatment in moderate (BMI > 30) as well as severe obesity. Reductions in comorbidities, such as diabetes and hypertension, also occur. Bariatric procedures were assessed, but some comparisons were assessed by just one trial. The limited evidence suggests that weight loss following gastric bypass is greater than vertical banded gastroplasty or adjustable gastric banding, but similar to isolated sleeve gastrectomy (SG) and banded gastric bypass. Isolated SG appears to result in greater weight loss than adjustable gastric banding. Evidence comparing vertical banded gastroplasty with adjustable gastric banding was found to be inconclusive.

O’Brien and colleagues: O’Brien et al. (2006) conducted a systematic review of studies evaluating medium-term weight loss after bariatric surgical procedures. Procedures examined in the 43 studies included LAGB (n=18), BPD with and without DS (n=7), and RYGBP (n=18). Of the LABG reports, 12 provided data on the LABAND, five on the Obtech® band (Ethicon Endo-Surgery, Inc., Cincinnati, OH), and one study included both devices. Pooled data for all procedures showed a mean EWL in the range of 54–67% with no evidence of loss of effect at 10 years. It was concluded that all current bariatric operations lead to major weight loss in the medium term. BPD and banded RYGBP appear to be more effective than both RYGBP and LAGB, which are equal in the medium term (O’Brien, et al., 2006).

Centers for Medicare and Medicaid Services (CMS): In February 2006, CMS issued an updated coverage decision for bariatric surgery. Based on their analysis of the medical literature, it was determined that the evidence is adequate to conclude that open and laparoscopic RYGB, laparoscopic adjustable gastric banding (LAGB), and open and laparoscopic bilipancreatic diversion with duodenal switch (BPD/DS) are reasonable and necessary for Medicare beneficiaries who have a BMI ≥ 35, have at least one comorbidity related to obesity, and have been previously unsuccessful with medical treatment for obesity. According to CMS, medical treatment which includes dietary manipulation, behavior modification and medication, should be routinely attempted either individually or in combination and shown to be unsuccessful prior to considering a patient for bariatric surgery. There are no consistent standards in the literature regarding the optimal length of a medical treatment trial; however, 6–12 months is believed to be a reasonable time frame.

Reanalysis of the data on surgical volume identified surgical experience as a significant factor in safety for bariatric surgery at both facility and surgeon levels. Based on this finding, CMS modified their proposed decision
to now provide coverage for patients age 65 and older as long as the bariatric procedures are performed in facilities that are most likely to achieve better outcomes. CMS has determined that covered bariatric surgery procedures are reasonable and necessary only when performed at facilities that are certified by the American College of Surgeons (ACS) or by the ASBS as a Bariatric Surgery Center of Excellence (BSCOE).

**California Technology Assessment Forum (CTAF):** Tice (2004) conducted a systematic review of evidence for the use of BPD/DS. Uncontrolled and case series describing several variations of the procedure were identified. There were no trials using randomized controls that compared BPD/DS to RYGB. The author concluded that, while case series indicate the degree of weight loss achieved with BPD/DS is comparable to that of RYGB, it is not possible to draw any firm conclusions regarding the relative benefits and harms of the two procedures. It was recommended that BPD/DS does not meet the technology assessment criteria for safety, effectiveness and improvement in health outcomes.

**Buchwald and colleagues:** Buchwald et al. (2004) conducted a systematic review and meta-analysis to determine the impact of bariatric surgery on weight loss, operative mortality outcome, and four obesity comorbidities (diabetes, hyperlipidemia, hypertension and obstructive sleep apnea). The authors concluded, “Bariatric surgery in morbidly obese individuals reverses, eliminates, or significantly ameliorates diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea. These benefits occur in the majority of patients who undergo surgery” (Buchwald, et al., 2004). The authors further state that resolution of diabetes was found to be more prevalent in patients who underwent malabsorptive procedures and mixed malabsorptive/restrictive gastric bypass than in those who had restrictive-only procedures, gastroplasty and gastric banding.

**Agency for Healthcare Research and Quality (AHRQ) Evidence Report:** In October 2004, the Agency for Healthcare Research and Quality of the U.S. Department of Health and Human Services released an evidence report on the surgical and pharmacological treatment of obesity. The detailed report drew the following conclusions regarding surgery:

- Bariatric surgical treatment results in greater sustained weight loss than nonsurgical treatments in very obese individuals (BMI ≥ 40), resulting in improved health outcomes (reduction in diabetes and sleep apnea, improved quality of life). While not conclusive, the data suggest greater sustained weight loss for bariatric surgical treatment than for nonsurgical treatment in patients with BMI between 35 and 40.
- RYGB, VBG, and adjustable banding procedures all result in substantial weight loss.
- RYGB results in greater weight loss than VBG in severely obese individuals.
- Postoperative mortality rates of less than one percent have been achieved by a number of surgeons and bariatric surgical centers. The postoperative mortality rate in other settings may be higher.
- Few clinical trials have compared outcomes among different bariatric surgical procedures. The existing data suggest the possibility of clinically important differences in the proportion of patients reporting various complications and adverse events among those treated with RYGB, VBG, and adjustable banding procedures.
- Laparoscopic procedures result in fewer wound complications or incisional hernias than open procedures.
- The actual proportions of patients who experience some complications of bariatric surgery may be quite substantial, greater than 20 percent (although most are minor in severity)” (Shekelle, et al., 2004).

**Blue Cross Blue Shield Technology Evaluation Center (TEC):** The TEC (2007) conducted an evaluation of the evidence on LAGB and concluded that the procedure “meets the TEC criteria when performed in appropriately selected patients, by surgeons who are adequately trained and experienced in the specific techniques used, and in institutions that support a comprehensive bariatric surgery program, including a long-term monitoring and follow-up post-surgery” (BCBSA TEC, 2007).

**Bariatric Surgery: Impact on Health Outcomes**
The potential benefits of bariatric surgery on health outcomes include the following:

- The increase in reported morbidity associated with obesity is thought to be mediated primarily by insulin resistance, diabetes, hypertension and lipid disturbances (Sjöstrom, et al., 2004).
- Diet therapy alone in the absence of surgery is relatively ineffective in treating obesity over the long term (Buchwald, et al., 2004).
• Severely obese patients who undergo bariatric surgery achieve greater short-, intermediate- and long-term (i.e., 10 years) weight loss, more physical activity and lower energy intake than severely obese patients treated with conventional medical interventions, such as very low-calorie diets and pharmacotherapy (Sjöstrom, et al., 2004; Buchwald, et al., 2004).
• Intermediate- and long-term (i.e., 10 years) incidence rates of recovery from risk factors such as diabetes, hypertriglyceridemia, low levels of high-density lipoprotein cholesterol, hypertension, hyperlipidemia and hyperuricemia are more favorable in surgically-treated patients than in nonsurgical, severely obese patients (Sjöstrom, et al., 2004; Buchwald, et al., 2004).
• Bariatric surgery reverses, eliminates or significantly improves risk factors of diabetes, hyperlipidemia, hypertension and obstructive sleep apnea (Buchwald, et al., 2004).
• Severely obese diabetic individuals treated with bariatric surgery have shown an 80% reduction in mortality (Sjöstrom, et al., 2004).
• Weight-loss surgery has been reported to reduce the relative risk of death by 89% with an absolute mortality reduction of 5.49% (Christou, et al., 2004).
• Gastric bypass has been reported to result in more favorable overall health outcomes (i.e., weight loss, risk factor recovery/reduction) relative to other surgical interventions, such as banding procedures (Buchwald, et al., 2004).

Buchwald et al. (2009) performed a meta-analysis of 19 studies with 43 treatment arms and 11,175 patients to determine the impact of bariatric surgery on type 2 diabetes in association with the procedure performed and the weight reduction achieved. The included studies reported both weight loss and diabetes resolution separately for the 4070 diabetic patients. At baseline, the mean age was 40.2 years with a mean BMI of 47.9 kg/m², and 10.5% had previous bariatric procedures. Meta-analysis of weight loss was 38.5 kg or 55.9% excess weight loss (EWL). Overall, 78.1% of diabetic patients had complete resolution, and diabetes was improved or resolved in 86.6% of patients. Weight loss and diabetes resolution were greatest for patients undergoing biliopancreatic diversion with duodenal switch (BPD/DS), followed by gastric bypass, and least for banding procedures. In the studies reporting only diabetic patients, 82% of patients had resolution of the clinical and laboratory manifestations of diabetes in the first two years after surgery, and 62% remained free of diabetes more than two years after surgery (80% and 75% for the total group) (Buchwald, et al., 2009).

Gracia et al. (2009) conducted a retrospective cohort study of different procedures for morbid obesity: open vertical banded gastroplasty (VBG) (n=125), open Scopinaro biliopancreatic diversion (BPD) (n=150), open modified BPD (i.e., common limb 75 cm; alimentary limb 225 cm) (n=100), and laparoscopic Roux-en-Y gastric bypass (LRYGB) (n=115). Mean follow-up was: VBG 12 years, BPD seven years, and LRYGB 4 years. An excellent initial weight loss was observed at the end of the second year of follow-up in all techniques, followed by regain of weight observed in the VBG and LRYGB groups. Patients in the BPD groups maintained weight loss results. Mortality was: VBG 1.6%, BPD 1.2%, and LRYGB 0%. Early postoperative complications were: VBG 25%, BPD 20.4%, and LRYGB 20%. Late postoperative morbidity was: protein malnutrition 11% in Scopinaro BPD, 3% in modified BPD group, and no cases reported either in VBG group or LRYGB group; iron deficiency 20% VBG, 62% Scopinaro BPD, 40% modified BPD, and 30.5% LRYGBP. Conversion to gastric bypass or to BPD was needed for 14.5% of VBG group due to 100% weight regain or vomiting. For those in the Scopinaro BPD group, revision surgery was needed to lengthen the common limb to 100 cm in 3.2% of cases due to severe protein malnutrition. Revision surgery to distal LRYGBP (common limb 75 cm) was required for 0.8% of LRYGBP patients due to 100% weight regain. It was noted that the more complex bariatric procedures increase effectiveness but also increase morbidity and mortality. In the opinion of these investigators, “LRYGB is safe and effective for the treatment of morbid obesity. Modified BPD (75-225 cm) can be considered for the treatment of superobesity (BMI > 50 kg/m²), and restrictive procedures such as VBG should only be performed in well-selected patients due to high rates of failure in long-term follow-up” (Gracia, et al., 2009).

Adams et al. (2007) conducted a retrospective cohort study to compare long-term rates of death from any cause and from specific causes in subjects who had undergone gastric bypass surgery compared to a group of severely obese controls. A total of 7925 surgical patients and 7925 severely obese control subjects were matched for age, sex, and BMI. The mean BMI differed significantly between the surgery group and the control group (p<0.001). During a mean follow-up of 7.1 years, adjusted long-term mortality from any cause in the surgery group decreased by 40%, as compared to the control group (p<0.001). Cause-specific mortality in the surgery group decreased by 56% for coronary artery disease (p=0.006), by 92% for diabetes (p=0.005), and by 60% for cancer (p<0.001). The estimated number of lives saved after a mean follow-up of 7.1 years was 136 per
evidence (n=24 studies) on efficacy, safety, and comparative effectiveness of various types of bariatric surgery. Maglione et al. (2013) performed an Agency for Healthcare Research and Quality (AHRQ) review of the literature. Bariatric surgery, particularly Roux-en-Y gastric bypass (n=48) or sleeve gastrectomy (n=49), has been shown to improve glycemic control and weight reduction compared to intensive medical therapy alone. Study results indicate that for obese patients with uncontrolled type 2 diabetes, bariatric surgery was associated with improved glycemic control and weight reduction compared to intensive medical therapy alone. It was noted that limitations to the study include the unknown baseline health status of patients seeking bypass surgery compared to that of control subjects. Also, the risk of death according to the amount of weight lost could not be analyzed as data on weight at time of death was unavailable (Adams, et al., 2007).

Sjöström et al. (2007) conducted a prospective, matched, surgical interventional trial, referred to as the Swedish Obese Subjects study, which involved 4047 obese subjects. Of these subjects, 2010 underwent bariatric surgery (surgery group) and 2037 received conventional treatment (matched control group). A total of 376 subjects underwent nonadjustable or adjustable banding, 1369 underwent vertical banded gastroplasty, and 265 received gastric bypass. For adjustable banding, the Swedish adjustable Gastric Band was used. Outcome measures included weight change and overall mortality during an average of 10.9 years of follow-up. Vital status was known for all but three subjects at the time of the analysis. In the surgery group, participation rates of subjects at follow-up examination at two, 10, and 15 years were 94%, 84%, and 66%, respectively. Corresponding rates for subjects in the control group were 83%, 75% and 87%. The average weight change in control subjects was less than +/-2% during the period of up to 15 years during which weights were recorded. At 10 years, the weight losses from baseline were stabilized at 25% after gastric bypass, 16% after vertical-banded gastroplasty, and 14% after banding. There were 129 deaths in the control group and 101 deaths in the surgery group. The most common causes of death were myocardial infarction which occurred in 25 subjects in the control group and 13 subjects in the surgery group. The most common cause of death from noncardiovascular causes (control group [n=47]; surgery group [n=29]). The main limitation of the study is the lack of randomization, however it is questionable whether randomization is feasible in bariatric surgery trials designed to study mortality. Although study results indicate that bariatric surgery is associated with a reduction in overall mortality, it is undetermined whether the favorable survival effect is explained by weight loss or by other beneficial effects of the surgical procedure (Sjöström, et al., 2007).

The National Institutes of Diabetes and Digestion and Kidney Disease (NIDDK) has sponsored the Longitudinal Assessment of Bariatric Surgery (LABS) program. This program involves six clinical centers that have expertise in relevant fields including bariatric surgery, obesity research, endocrinology, epidemiology, and outcomes research. The purpose of the LABS program is to plan and conduct studies that will analyze the risks and benefits of bariatric surgery and its impact on the health and well-being on patients with severe obesity as well as to identify the types of patients who are most likely to benefit from bariatric surgery (NIDDK, 2007).

**Bariatric Surgery for the Treatment of Type 2 Diabetes Mellitus (T2DM)**

Bariatric surgery is currently being evaluated as a treatment and potential cure for T2DM. Studies reporting the results of bariatric surgery on T2DM have primarily included morbidly obese patients (i.e., a BMI ≥ 40 or a BMI 35–39.9 with a clinically significant obesity-related comorbidity) and have demonstrated that obese diabetic patients who undergo bariatric surgery experience complete T2DM remission. Fewer studies have investigated the safety and efficacy of bariatric surgery, also referred to as metabolic surgery, in patients with a BMI less than 35 (class I obesity).

**Literature Review:** Schauer et al. (2014) published an RCT (n=150) of obese patients with uncontrolled type 2 diabetes randomized to receive either intensive medical therapy alone (n=40) or intensive medical therapy plus Roux-en-Y gastric bypass (n=48) or sleeve gastrectomy (n=49). The Surgical Treatment and Medications Potentially Eradicate Diabetes Efficiently (STAMPEDE) trial included patients between the ages of 20-60 years, with a glycated hemoglobin level >7.0%, and a BMI of 27-43. The primary outcome was a glycated hemoglobin level of 6.0% or less, with or without the use of diabetes medications. A total of 91% of the patients completed 36 months of follow-up. At three years, the criterion for the primary end point was met by 5% of the patients in the medical-therapy group, compared to 38% of those in the gastric-bypass group (p<0.001) and 24% of those in the sleeve-gastrectomy group (p=0.01). Study results indicate that for obese patients with uncontrolled type 2 diabetes, bariatric surgery was associated with improved glycemic control and weight reduction compared to intensive medical therapy alone. It was noted that limitations to the study include an inadequate sample size and duration to detect differences in the incidence of diabetes complications, such as myocardial infarction, stroke, or death. The study protocol specifies further follow-up at years for all patients, which should allow additional assessment of even longer-term efficacy (Schauer, et al. 2014).

Maglione et al. (2013) performed an Agency for Healthcare Research and Quality (AHRQ) review of the evidence (n=24 studies) on efficacy, safety, and comparative effectiveness of various types of bariatric surgery.
for treating adult patients with a body mass index (BMI) of 30.0 to 34.9 kg/m² and diabetes or impaired glucose tolerance (IGT). The review compared effectiveness of surgery versus nonsurgical interventions in this population and included primarily observational studies (n=19 studies), in addition to trials comparing different procedures (n=2 studies), and surgical versus nonsurgical interventions (n=3 studies). Studies for the analysis had to report on LAGB, RYGB, BPD/DS, sleeve gastrectomy, or nonsurgical treatment, and had to include patients with a BMI of at least 30 kg/m² but less than 35 kg/m² with diabetes or IGT. Excluded were nonsurgical studies already included in previous systematic reviews or with less than one year follow-up, those with no outcomes of efficacy, effectiveness, or safety/adverse events, and studies with a sample size of less than three. Outcomes measured were weight and blood glucose levels.

Based primarily on glucose control outcomes, moderate strength evidence of efficacy of bariatric surgery in treating diabetes in patients with a BMI of at least 30 but less than 35 kg/m² in the short term was found. At one-year follow-up, surgery patients show much greater weight loss than usually seen in studies of diet, exercise, or other behavioral interventions. The overall evidence was rated as moderate due to paucity of data—three randomized controlled trials (RCTs) directly compared surgical with nonsurgical interventions, and two came from the same group of researchers. Observational data, which start as low strength evidence, were upgraded due to consistency of results regarding BMI and blood sugar. The strength of evidence of efficacy for RYGB, LAGB, and SG in treating diabetes and IGT in patients with a BMI of between 30 and 35 in the short term (i.e., up to 2 years) was rated as moderate. For BPD, both the number of studies and their sample sizes are much lower; thus the strength of evidence of efficacy for this procedure was rated low. Evidence on comparative effectiveness of surgical procedures is insufficient. The strength of evidence for short-term harms was low for all four surgical procedures and insufficient for long-term adverse events.

It was concluded that the literature on bariatric surgery for diabetes or IGT patients with BMI of at least 30 kg/m² and less than 35 kg/m² has many limitations. There is minimal data on long-term efficacy and safety, as few studies of this target population have long-term follow-up. No evidence was found on major clinical endpoints such as all-cause mortality, cardiovascular mortality or morbidity, or peripheral arterial disease. The studies of bariatric surgery in this population have measured only intermediate or surrogate endpoints regarding glucose control. While control of glucose is certainly important, the available evidence from the diabetes literature indicates it may be premature to assume that controlling glucose to normal or near normal levels completely mitigates the risk of microvascular and macrovascular events. Thus, claims of a “cure” for diabetes based on glucose control within one or two years require longer term data before they can be substantiated (Maglione, et al., 2013).

The Blue Cross Blue Shield Technology Evaluation Center (TEC) (2013) conducted an assessment of the evidence to determine whether bariatric surgery improves outcomes for diabetic patients with BMI less than 35. Studies were selected that used bariatric surgery to treat diabetic patients with BMI less than 35 and reported on one or more relevant outcomes related to the remission or change in severity of diabetes. A total of 16 case series and observational studies with patient population ranging from 12-202 and an average follow-up period of 20 months were included in the assessment. There were no randomized trials comparing bariatric surgery to medical treatment for diabetic subjects with BMI less than 35. Diabetes remission rates and other outcomes in subjects undergoing gastric bypass were reported in nine studies, primarily case series. Remission rates varied between 48% and 100% at follow-up times of one year and beyond. One study, an RCT of gastric bypass versus sleeve gastrectomy, reported diabetes remission rates of 93% for gastric bypass versus 47% for sleeve gastrectomy at one year. Gastric bypass for the treatment of type 2 diabetes in patients with a BMI less than 35 met the TEC criteria. However, this determination was based on a lower level of evidence including studies with small patient populations and short-term follow-up. Except for gastric bypass, insufficient evidence was found to come to firm conclusions regarding the efficacy of bariatric procedures for diabetes in patients with BMI less than 35 (BCBSA, 2013).

Ikramuddin et al. (2013) conducted a multicenter unblinded randomized trial (n=120) to compare Roux-en-Y gastric bypass with lifestyle and intensive medical management (n=60) with intensive management alone (n=60). Subjects with a hemoglobin A1c (HbA1c) level of ≥ 8.0%, BMI between 30.0 and 39.9, C peptide level of > 1.0 ng/mL, and type 2 diabetes for at least six months were included. The primary end-point was a composite goal of HbA1c < 7.0%, low-density lipoprotein cholesterol < 100 mg/dL, and systolic blood pressure < 130 mm Hg. Secondary outcome measures included weight loss, medication use, and adverse events. After 12-months of follow-up, 28 participants (49%) in the gastric bypass group and 11 (19%) in the lifestyle-medical management group achieved the primary end points (p<0.01). Participants in the gastric bypass group required
3.0 fewer medications and lost 26.1% vs 7.9% of their initial body weight compared with the lifestyle-medical management group. There were 22 serious adverse events in the gastric bypass group, including a single cardiovascular event, and 15 in the lifestyle-medical management group. The gastric bypass group experienced more nutritional deficiency than the lifestyle-medical management group. Study limitations include the relatively small patient population and short-term follow-up.

A California Technology Assessment Forum (CTAF) document by Tice (2012) reviewed the evidence on bariatric surgical procedures for the treatment of T2DM, specifically addressing whether the evidence supports extending the use of bariatric surgery to patients with T2DM and a BMI < 35 kg/m². Studies reviewed for this subset of patients included a systematic review that summarized the data from 29 small studies including 675 patients with T2DM and a pre-operative BMI < 35 kg/m². The majority of the studies reported outcomes at one year or shorter follow-up. The average BMI of the study subjects dropped from 29.9 to 24.8 kg/m² over a variable length of follow-up. Fasting glucose decreased from 208 to 114 mg/dL and HbA1c decreased from 8.9 to 6.4%. The report also included an RCT, observational studies (n=2) and a single case series. In general the studies were found to be small, methodologically weak, with short follow-up. The report concluded that evidence base for patients with diabetes and a BMI < 35 kg/m² is less robust than the evidence for those with diabetes and a BMI > 35 kg/m². In the case series and comparative studies, bariatric surgery was found to improve glycemic control and diabetes remission rates more than would be expected with medical therapy. However, there are fewer studies, shorter follow-up and no randomized trials comparing bariatric surgery to medical therapy. It was stated that it remains unclear whether the benefits of bariatric surgery for individuals with diabetes outweigh the harms for less obese patients. There are no long-term studies documenting a reduction in cardiovascular outcomes in patients with a BMI < 35 kg/m². Observational studies and one randomized trial without a medical therapy control arm have documented significant improvements in glycemic control and high rates of diabetes remission in this population. But less obese individuals might have less overall benefits from weight loss surgery and may be at higher risk for complications due to excessive weight loss. High quality comparative studies are needed to adequately assess the net benefits of surgery (Tice, 2012).

Schauer et al. (2012) conducted a randomized non-blinded, single-center trial (n=150) to assess the efficacy of intensive medical therapy alone versus medical therapy plus Roux-en-Y gastric bypass or sleeve gastrectomy in obese patients with uncontrolled type 2 diabetes. The mean BMI was 36; 51/150 patients had a BMI less than 35. The average glycated hemoglobin level was 9.2±1.5%. The primary end point was the proportion of patients with a glycated hemoglobin level of ≤ 6.0% 12 months after treatment. Of the 150 patients, 93% completed 12 months of follow-up. The proportion of patients with the primary end point was 12% (5 of 41 patients) in the medical-therapy group versus 42% (21 of 50 patients) in the gastric-bypass group (p=0.002) and 37% (18 of 49 patients) in the sleeve-gastrectomy group (p=0.008). Glycemic control improved in all three groups, with statistical significance in the gastric-bypass (p<0.001), and sleeve-gastrectomy (p=0.003) groups. The wide range of BMI levels and short-term follow-up limit the ability to draw conclusions that are specific to class I obese patients.

Lee et al. (2011) randomized 60 patients with T2DM, HbA1c > 7.5%, c-peptide ≥ 1.0, and a BMI > 25 and < 35 kg/m² to either gastric bypass (n=30) or sleeve gastrectomy (n=30) performed laparoscopically. The primary outcome was remission of diabetes defined as HbA1c < 6.5% and fasting glucose < 126 mg/dL on no diabetes medications at the one-year follow-up. Follow-up was 100% in both groups at one year. The average age of participants was 45 years, with an average BMI of 30 kg/m² (range 25-34), and an average HbA1c of 10.0%. The diabetes remission rate was higher in the RYGB group (93% versus 47%, p=0.02). The average reduction in HbA1c at one year was also higher in the RYGB group (4.2% versus 3.0%, p<0.001). At the one year follow-up, the average HbA1c was lower in the RYGB group (5.7% versus 7.2%, p<0.001), as was the average fasting glucose level (99 versus 140, p<0.001), the LDL-cholesterol (97 versus 137, p<0.001), and BMI (22.8 versus 24.4, p=0.009). This study is limited by the small number of participants and short-term follow-up.

Dixon et al. (2008) conducted an unblinded RCT to determine if surgically induced weight loss results in better glycemic control and less need for diabetes medications than conventional approaches to weight loss and diabetes control. This study included 60 obese patients with a BMI range of 30–40, recently diagnosed (i.e., <2 years) type 2 diabetes, and with no evidence of renal impairment or diabetic retinopathy. The surgical group (n=30) underwent laparoscopic adjustable gastric banding (LAGB) along with conventional diabetes care and the conventional-therapy group received diabetes therapy with a focus on weight loss by lifestyle change. The primary outcome measure was remission of type 2 diabetes demonstrated by a fasting glucose level <126 mg/dL (7.0 mmol/L) and glycated hemoglobin [HbA1c] value <6.2% while taking no glycemic therapy. Secondary
measures included weight and components of the metabolic syndrome. Of the 60 patients enrolled, 55 (92%) completed the two-year follow-up. Remission of type 2 diabetes was achieved by 22 (73%) in the surgical group (n=30) and four (13%) in the conventional-therapy group (p<0.001). Relative risk of remission for the surgical group was 5.5 (95% confidence interval, 2.2-14.0). The surgical group achieved a mean 20% body weight loss at two years compared to a 1.4% body weight loss among the conventional-therapy group (p<0.001). The reduction in metabolic syndrome was significant in the surgical group (p<0.001), but not in the conventional-therapy group (p=0.23). It was noted that although study results suggest that patients who received surgical intervention were more likely to achieve remission of type 2 diabetes through greater weight loss, these results need to be confirmed in a larger study with a more diverse population and an assessment of long-term efficacy (Dixon, et al., 2008).

Case series with patient populations ranging from 18─42 and follow-up periods of 12─24 months have also demonstrated promising results, with reversal rates of type 2 diabetes mellitus ranging from 62%─88%. However these studies are limited by their design and short-term follow-up (Gianos, et al., 2012; Abbatini, et al., 2012; Huang, et al., 2011; Boza, et al., 2011; Serrot, et al., 2011).

According to guidelines from the American Association of Clinical Endocrinologists (AACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMBS), "The beneficial effect of bariatric surgery on T2DM is one of the most important outcomes observed. Control rates for most procedures currently performed vary from 40% to 100%. Gastric bypass and malabsorptive procedures offer the highest rates of remission of T2DM. Improvements in fasting blood glucose levels occur before significant weight loss. Insulin-treated patients experience substantial decreases in insulin requirements, with the majority of patients with T2DM able to discontinue insulin therapy by six weeks after bariatric surgery. Euglycemia has been maintained up to 14 years after RYGB, a superior outcome when compared with solely gastric restrictive procedures. BPD and BPD/DS may be even more effective at improvement of the metabolic abnormalities of T2DM, leading to discontinuation of glucose-lowering therapy in most patients. The LAGB procedure has also been shown to improve T2DM, although at a slower rate (64% to 71% remission rates within the first year) than RYGB, BPD, or BPD/DS" (Mechanik, et al., 2008).

The 2013 updated guidelines from the American Association of Clinical Endocrinologists (AACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMBS) state that patients with BMI of 30-34.9 kg/m² with diabetes or metabolic syndrome may also be offered a bariatric procedure although current evidence is limited by the number of subjects studied and lack of long-term data demonstrating net benefit. There is insufficient evidence for recommending a bariatric surgical procedure specifically for glycemic control alone, lipid lowering alone, or cardiovascular disease risk reduction alone, independent of BMI criteria Mechanick, et al., 2013).

Gastric bypass or other bariatric procedures performed as a treatment for diabetes mellitus in the absence of obesity has not been adequately studied. The risk/benefit ratio of surgery in less obese (BMI 30-35 kg/m²) populations has also not been fully explored. There is currently insufficient evidence to support the safety and effectiveness of bariatric surgery solely as a treatment for T2DM in individuals with a BMI less than 35.

Reoperation/Repeat Bariatric Surgery

Previous bariatric operative approaches may fail for functional or technical reasons, causing inadequate weight loss or severe complications. The literature indicates that reoperative procedures may be required for metabolic complications of jejunoileal bypass, obstruction, alkaline or acid reflux esophagitis, band erosion, stricture, anastomatic ulcer, or gastric pouch dilatation (may occur following gastric restrictive procedures). In addition, it has been reported that many patients do not achieve adequate weight loss with certain gastric restrictive procedures, such as vertical banded gastroplasty, even when fully compliant with postoperative nutritional and exercise recommendations. In general, up to two years may be required for patients to reach their maximum weight loss following bariatric surgery. Follow-up bariatric surgery, such as conversion from adjustable banding to Roux-en-Y, may be proposed when adequate weight loss has not occurred after one to two years following the initial surgery. Less commonly performed is the revision of a gastric bypass via placement of an adjustable gastric band. This revision, referred to as “band over bypass” or “salvage banding”, is a less invasive option to control pouch size compared to the other limited options such as a conversion to a longer limb bypass procedure with the associated adverse effect of severe malnutrition. Further weight loss after salvage banding has been reported in the literature as varying from 55.9%–94.2% excess body mass index loss (EBMIL) after 12–42 months of follow-up (Vijgen, et al., 2012).
Although there is no consensus on the definition of "adequate weight loss," bariatric surgery is considered by some experts to be successful when a patient loses at least 50% of excess weight or achieves body weight that is within 30% of ideal. Inadequate weight loss due to patient noncompliance with the postoperative nutrition and exercise program is not considered a medically necessary indication to undergo revision surgery or conversion to another procedure. In general, revision surgery due to inadequate weight loss is reserved for those individuals in whom the original surgery was initially successful in achieving weight loss and who, due to the technical failure of the original procedure (e.g., pouch dilatation), have failed to achieve adequate weight loss in the two years following the original surgery. Patients undergoing revision procedures should also have demonstrated that they have been fully compliant with their prescribed postoperative diet and exercise programs.

According to the 2013 updated guidelines from the American Association of Clinical Endocrinologists (AACE), The Obesity Society (TOS), and the American Society for Metabolic and Bariatric Surgery (ASMBS), revision of a bariatric surgical procedure can be recommended when serious complications related to previous bariatric surgery cannot be managed medically. Reversal of a bariatric surgical procedure is recommended when serious complications related to previous bariatric surgery cannot be managed medically and are not amenable to surgical revision (Mechanick, et al., 2013).

Reoperation by surgical reversal (i.e., "takedown") or surgical revision of bariatric surgery is generally considered to be medically necessary at any time following the original surgery when the patient experiences complications from the original surgery, such as stricture, obstruction, pouch dilatation, erosion or band slippage. In addition, reoperation for inadequate weight loss is generally considered to be medically necessary if the original procedure was performed at least one year prior to the reoperation date and the patient has not achieved adequate weight loss despite being compliant with postoperative nutritional and exercise recommendations. Conversion from a gastric restrictive procedure to a Roux-en-Y is a common reoperative technique.

**Cholecystectomy at the Time of Bariatric Surgery**

It has been shown that there is a moderate correlation between obesity and the development of gallstones, with the risk of cholelithiasis rising as BMI increases. Furthermore, evidence in the scientific literature suggests that the rapid weight loss which occurs following certain bariatric surgical procedures increases cholesterol load, thereby increasing the risk for gallstone formation. For these reasons, some surgeons advocate the routine removal of asymptomatic normal gallbladders at the time of bariatric surgery (specifically gastric bypass procedures). It has been suggested that patients undergoing gastric bypass are at a greater risk than with other procedures, such as gastric banding, due to the malabsorption and early and rapid postoperative weight loss associated with this procedure. The issue of performing routine prophylactic cholecystectomy concurrently with bariatric surgery continues to be debated, however. Many experts contend that performing cholecystectomy on nondiseased, normal-appearing gallbladders is not recommended and places unnecessary risk on the patient (Sreenarasimhaiah, 2004; Villegas, et al., 2004). Combining procedures increases operative time and has been reported to lengthen hospital stay significantly (Hamad, et al., 2003). Additionally, many of these individuals who do form gallstones do not develop symptoms that will ultimately lead to the need to remove the gallbladder. O'Brien and Dixon (2003) reported that only 6.8% of patients undergoing laparoscopic adjustable gastric banding (LAGB) developed symptomatic gallstones necessitating cholecystectomy. Rather than surgical removal of the nonsymptomatic gallbladder, some surgeons support the prophylactic use of ursodiol, a bile acid which prevents gallstone formation.

Fuller et al. (2007) reported on 144 consecutive patients undergoing RYGB who were routinely screened for cholelithiasis by ultrasound. The mean age was 43 years and the mean BMI was 46 kg/m². A total of 29 patients had a history of prior cholecystectomy. Cholelithiasis was diagnosed preoperatively in 22 of the remaining 115 patients. Of those 22 patients, nine (41%) were symptomatic and underwent concurrent cholecystectomy and RYGB. The remaining 13 patients (59%) had asymptomatic cholelithiasis preoperatively but did not undergo cholecystectomy at the time of surgery. Patients who did not have cholecystectomy were managed with ursodiol for 6 months postoperatively. Only one of these asymptomatic patients subsequently developed symptoms requiring cholecystectomy at up to one-year follow-up. This incidence did not reach statistical significance (p=0.59), suggesting that the relative risk of requiring a cholecystectomy after RYGB in the absence of preoperative symptoms is small (Fuller, et al., 2007).
Caruana et al. (2005) reported on a series of 125 patients who underwent Roux-en-Y gastric bypass (RYGB) and were not treated with ursodiol postoperatively. These patients had no palpable gallstones at the time of surgery and were followed for at least 16 months (range 16–48 months) after RYGB. Cholecystectomy for symptomatic stones was performed in 4.9% of patients during the first year of follow-up and in an additional 5% of patients within the second year of follow-up. There were no serious complications from the stones or the cholecystectomy. It was noted that prophylactic cholecystectomy would have been unnecessary in 115 of the 125 patients in this particular study group (Caruana, et al., 2005).

Villegas et al. (2004) attempted to determine the incidence of gallstone formation requiring cholecystectomy following laparoscopic Roux-en-Y. Of the 289 patients studied, 189 patients had no stone formation when examined intraoperatively. Of these 189 individuals, 151 patients had postoperative ultrasounds at six-month follow-up. A total of 33 patients developed gallstones (22%), and 8% had biliary sludge. Only 11 patients experienced gallstone-related symptoms requiring cholecystectomy (Villegas, et al., 2004).

The published, peer-reviewed scientific literature indicates that prophylactic removal of a normal gallbladder (i.e., no evidence of gallstones or biliary sludge demonstrated on ultrasound or other diagnostic testing) is not considered medically necessary when performed concurrently with bariatric surgery, including gastric bypass. The impact on health outcomes has not been established through well-designed studies. Cholecystectomy performed concurrently with bariatric surgery is considered medically necessary when there is preoperative or intraoperative evidence of gallstones or biliary sludge on diagnostic study or when there is a recent history of cholecystitis.

Routine Liver Biopsy at the Time of Bariatric Surgery
Nonalcoholic fatty liver disease (NAFLD), generally considered a clinically benign finding, is common in the general adult population, with a reported prevalence of approximately 23% in the U.S. It has been estimated that NAFLD can be found in 65% of obese patients (Beymer, et al., 2003). A variant of NAFLD, nonalcoholic steatohepatitis (NASH), has been reported to predispose individuals to liver fibrosis, and ultimately, cirrhosis. Often clinically hidden, NASH can be present despite liver function studies within acceptable parameters. Few studies, however, have reported on the role of NASH in obese patients. There is very little information available on the prevalence of asymptomatic liver disease in morbidly obese patients (Beymer, et al., 2003). The exact role of NASH as an independent predictor in advanced liver disease has not been clearly established. It has been suggested that there may be several clinical triggers needed for NASH to progress to advanced liver disease including, but not limited to, type 2 diabetes, high BMI, liver toxins, and alcohol consumption. Liver biopsy is currently used to confirm the diagnosis of NAFLD and to differentiate between NAFLD and NASH. However there are no clear guidelines as to when and in whom liver biopsy is necessary (Duvinjak, et al., 2007).

Dolce et al. (2009) presented a series of 108 patients undergoing bariatric surgery who had routine intraoperative liver biopsy. The aim of this study was to determine the relationship between the intraoperative liver appearance and the histopathologic findings during laparoscopic bariatric surgery. An intraoperative liver visual score was recorded according to the size, tan-speckling, and contour. The liver histologic findings were categorized into 3 groups: (1) normal; (2) bland steatosis; and (3) nonalcoholic steatohepatitis (NASH). The liver visual score was compared with the liver histologic findings. The prevalence of NASH was found to be 23% (n=25). Of the 25 patients with NASH, 12 (48%) had normal-appearing livers. Of the 50 normal-appearing livers, 12 (24%) had NASH and 14 (28%) had bland steatosis. The authors noted that the correlation between the general appearance of the liver and the presence of NASH is poor, limiting the sensitivity of selective liver biopsy.

Shalhub et al. (2004) analyzed prospective data on 242 patients who underwent open and laparoscopic RYGB to determine the role of routine liver biopsy in managing bariatric patients. The same pathologist graded all liver biopsies as mild, moderate or severe steatohepatitis. NASH was defined as steatohepatitis without alcoholic or viral hepatitis. Consecutive liver biopsies were compared to those liver biopsies selected because of grossly fatty livers. Selective liver biopsies were performed in 86 of the first 174 patients and routine liver biopsies were done in the remaining 68 consecutive patients. The two groups were reported to have to have similar findings of steatosis, but more patients were categorized as having moderate and severe NASH based on routine liver biopsy compared to selective biopsy (p<0.05). Both groups had a similar prevalence of cirrhosis. There was no correlation found between BMI, abnormal liver tests, and the severity of NASH. Study results indicate that liver biopsy is the gold standard for diagnosing NASH. However, additional data from well-designed RCTs are needed to support the need for routine liver biopsy during bariatric surgical procedures.
Some surgeons support the use of concurrent routine liver biopsy in all patients undergoing bariatric surgery. Like prophylactic cholecystectomy, routine liver biopsy in the absence of clinical findings at the time of bariatric surgery continues to be debated. Just what role routine liver biopsy plays in patients undergoing bariatric surgery is not known. Impact on health outcomes has not been established through well-designed clinical trials. At this time, there is not sufficient evidence to support routine liver biopsy in patients undergoing bariatric surgery.

**Hiatal Hernia Repair at the Time of Bariatric Surgery**

A hiatal hernia occurs when part of the stomach pushes upward through the diaphragm. Hiatal hernias may be either sliding, in which the gastroesophageal junction itself slides through the defect into the chest, or non-sliding (paraesophageal), in which case the junction remains fixed while another part of the stomach moves up through the defect. Non-sliding or paraesophageal hernias can be dangerous as they may allow the stomach to rotate and obstruct.

Hiatal hernia is associated with obesity and gastroesophageal reflux disease (GERD) and its complications. Medical therapy for GERD includes medications that neutralize or reduce stomach acid. Surgery is generally reserved for emergency situations and for those who are not responsive to medications. Hiatal hernia repair surgery by laparoscopy, laparotomy or thoracotomy is often combined with surgery for GERD. Nissen fundoplication is one method of repair used to treat GERD when it is caused by a hiatal hernia.

Some physicians evaluate patients prior to bariatric surgery with an esophagogastroduodenoscopy or upper gastrointestinal study to detect conditions such as hiatal hernias and esophageal mucosal abnormalities related to gastroesophageal reflux (Mechanick, et al., 2008). Operable symptomatic patients with a paraesophageal hernia should undergo repair. The underlying surgical principles for successful repair include reduction of hernia contents, removal of the hernia sac, closure of the hiatal defect, and an antireflux procedure (Schieman, et al., 2009).

**Vena Cava Filter Placement at the Time of Bariatric Surgery**

Obesity and general surgery are risk factors for venous thromboembolism. Patients undergoing bariatric surgery are considered generally to be at moderate risk for lower extremity deep vein thrombosis (DVT) and pulmonary embolus (PE) may be the first manifestation of venous thromboembolism (VTE) and is the leading cause of mortality in experienced bariatric surgery centers. Obese patients undergoing bariatric surgery should receive preventive measures in the perioperative period. Early postoperative ambulation and perioperative use of lower extremity sequential compression devices are safe and suggested for all bariatric patients when feasible. Unless contraindicated, chemoprophylaxis using various anticoagulant regimens is an important adjunct to these methods which should be routinely administered to bariatric surgery patients. The possible role of inferior vena cava (IVC) filters remains controversial and recommendations regarding this issue have not been established (ASMBBS, 2007). Because of the long-term complications of permanent IVC filters, retrievable IVC filters may be an option for selected patients in whom an elevated risk of thromboembolism is limited to the early postoperative period (Hamad and Bergqvist, 2006).

The evidence evaluating the safety and effectiveness of prophylactic IVC filter placement with bariatric surgery is primarily in the form of small, uncontrolled studies. Trigilio-Black et al. (2007) evaluated IVC filter use for PE risk reduction in high-risk super morbidly obese bariatric surgery patients. In this cohort of patients (n=41) had a mean BMI of 64.2 +/- 12 kg/m² (range 47-105). IVC filters were inserted at the time of bariatric surgery according to the patient's risk factors, including immobility, previous DVT/PE, venous stasis, and pulmonary compromise. No instances of PE were documented, and no immediate or late complications related to filter placement occurred. DVT occurred in one patient, and one patient, with a BMI 105 kg/m², died secondary to rhabdomyolysis. Study limitations include the lack of randomization and small sample size. The authors noted that additional studies are needed to confirm the efficacy of IVC filter placement for PE risk reduction and related mortality in the super morbidly obese.

Obeid et al. (2007) conducted a retrospective study to evaluate whether prophylactic placement of an IVC filter in bariatric patients determined to be at high risk is effective in reducing their risk of PE. A total of 1851 patients were identified as low risk and did not receive an IVC filter. Among these patients, 12 DVTs, 11 PEs, and four deaths occurred. Of the 248 high-risk patients who received IVC filters, three DVTs, two PEs, and two deaths occurred. The difference in the rates of PE was not significant (p=0.69). According to the authors, study results
suggest that the use of prophylactic IVC filters reduces the risk of PE in high-risk patients to a rate comparable to the baseline risk of a low-risk group. The study is limited by its retrospective, nonrandomized design.

Halmi and Kolesnikov (2007) reported on 27 of 652 mini-open Roux-en-y gastric bypass (RYGB) patients who were at high risk for PE and received preoperative retrievable IVC filters placed by the interventional radiology two hours before bypass surgery. The mean BMI was 48.7 +/- 4.2 kg/m² (range 38-75). The indications for filter placement were previous DVT/PE, thrombophlebitis, a hypercoagulable state, pulmonary hypertension, an inability to ambulate, a body mass index >65 kg/m², and the presence of severe sleep apnea. Of the 27 filters, 26 were successfully removed during an outpatient procedure 18-21 days postoperatively. No thromboembolic complications occurred in this high-risk group. One retrievable filter was not removed because of prolonged hospitalization secondary to small bowel obstruction. Of the 625 patients who did not receive IVC filters preoperatively, two developed clinically significant PE and seven developed lower extremity DVT. It was noted that additional studies on larger clinical series are needed to prove the effectiveness of retrievable IVC filters in bariatric surgery (Halmi and Kolesnikov, 2007).

The AACE/ TOS/ ASMBS guidelines for the bariatric surgery patient state that "although randomized trials to support this action are lacking, prophylactic vena caval filter should be considered for patients with a history of prior PE, prior iliofemoral DVT, evidence of venostasis, known hypercoagulable state, or increased right-sided heart pressures" (Mechanick, et al., 2008). In the 2013 update to these guidelines it is stated that patients with a history of DVT or cor pulmonale should undergo an appropriate diagnostic evaluation for DVT as an element of medical clearance for bariatric surgery. According to the AACE/ TOS/ ASMBSS, prophylactic vena caval filter may present a greater risk than benefit in patients with a history of prior pulmonary embolus or DVT given the risks of filter-related complications including thrombosis (Mechanick, et al., 2013).

There is insufficient evidence in the published peer-reviewed medical literature to support routine prophylactic placement of IVC filters in all patients undergoing bariatric surgery. However, there is some evidence in the form of case series and professional society guidance to suggest that the procedure is appropriate in those bariatric surgery patients who are determined to be at high risk for venous thromboembolism (VTE).

Upper Endoscopy at the Time of Bariatric Surgery
The role of routine upper endoscopy in obese patients prior to bariatric surgery is controversial. The rationale for performing an upper endoscopy before bariatric surgery is to detect and/or treat lesions that might potentially affect the type of surgery performed, cause complications in the immediate postoperative period, or result in symptoms after surgery (American Society for Gastrointestinal Endoscopy [ASGE], 2008).

The American Association of Clinical Endocrinologists, The Obesity Society, and the American Society for Metabolic and Bariatric Surgery (AACE/TOS/ASMBS) guidelines for bariatric surgery state that all gastrointestinal symptoms should be evaluated and treated before bariatric surgery. According to these guidelines, although it is commonplace for surgeons to perform a routine upper gastrointestinal study or endoscopy to screen for peptic ulcer disease before many other types of surgical procedures, this practice has been questioned for bariatric surgery. After bariatric surgery, upper intestinal endoscopy is the preferred diagnostic procedure for the evaluation of persistent and severe gastrointestinal symptoms (e.g., nausea, vomiting, abdominal pain). In many circumstances, upper endoscopy can also incorporate a therapeutic intervention with transendoscopic dilation of a recognized stricture (Mechanik, et al., 2008).

In 2008, the ASGE issued a guideline on the use of endoscopy in the bariatric surgery patient. Recommendations include the following:

- An upper endoscopy should be performed in all patients with upper-gastrointestinal-tract symptoms who are undergoing bariatric surgery.
- Upper endoscopy should be considered in all patients undergoing Roux-en-Y gastric bypass (RYGB), regardless of the presence of symptoms.
- In asymptomatic patients who are undergoing gastric banding, a preoperative upper endoscopy should be considered to exclude large hernias that may change the surgical approach.
- An endoscopic evaluation is useful for diagnosis and management of postoperative bariatric surgical symptoms and complications.
The guideline does not discuss any indications for upper endoscopy performed during bariatric surgery.

Professional society guidance suggests that upper endoscopy is warranted when performed in symptomatic patients prior to bariatric surgery. Well-designed prospective studies are needed to further evaluate the utility of preoperative routine upper endoscopy in bariatric surgery patients. Upper endoscopy performed at the time of bariatric surgery is not supported in the peer-reviewed medical literature, and is not considered medically necessary.

**Professional Societies/Organizations**
The American Association of Clinical Endocrinologists, The Obesity Society, and the American Society for Metabolic and Bariatric Surgery (AACE/TOS/ASMBS) guidelines for bariatric surgery state that the best choice for any bariatric procedure (type of procedure and type of approach) depends on the available local-regional expertise (surgeon and institution), patient preferences, risk stratification, and other factors, with which the referring physician(s) must become familiar. Within the guidelines, the following bariatric procedures are categorized as investigational:

- gastric bypass with laparoscopic adjustable gastric banding (LAGB)
- robotic procedures
- endoscopic (oral)-assisted techniques
- gastric balloon
- gastric pacer
- vagus nerve pacing
- vagus nerve block
- sleeve gastrectomy

It is further stated that at this time there is insufficient conclusive evidence to recommend specific bariatric surgical procedures for the general severely obese population. If there is appropriate surgical and institutional expertise available, laparoscopic procedures should be selected over open procedures because of decreased postoperative complications. This approach applies for vertical banded gastroplasty, (LAGB), RYGB, and biliopancreatic diversion with duodenal switch (Mechanick, et al., 2008).

The following are recommended AACE/TOS/ASMBS selection criteria for bariatric surgery:

- Weight (adults): BMI ≥40 kg/m² with no comorbidities, BMI ≥35 kg/m² with obesity-associated comorbidity
- Weight loss history: failure of previous nonsurgical attempts at weight reduction, including nonprofessional programs (e.g., Weight Watchers, Inc)
- Commitment: expectation that patient will adhere to postoperative care; follow-up visits with physician(s) and team members; recommended medical management, including the use of dietary supplements; instructions regarding any recommended procedures or tests
- Exclusions: reversible endocrine or other disorders that can cause obesity; current drug or alcohol abuse; uncontrolled, severe psychiatric illness; lack of comprehension of risks, benefits, expected outcomes, alternatives, and lifestyle changes required with bariatric surgery

According to the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) guideline for clinical application of laparoscopic bariatric surgery, preoperative weight loss may be useful to reduce liver volume and improve access for laparoscopic bariatric procedures, but mandated preoperative weight loss does not affect postoperative weight loss or comorbidity improvements. Laparoscopic Roux-en-y gastric bypass (LRYGB), gastric banding by vertical banded gastroplasty or adjustable gastric banding, and biliopancreatic diversion with and without duodenal switch are established and validated bariatric procedures that provide effective long-term weight loss and resolution of co-morbid conditions. Laparoscopic sleeve gastrectomy (LSG) is validated as providing effective weight loss and resolution of comorbidities to 3-5 years. Laparoscopic revisional procedures may be performed safely, but with more complications than primary bariatric procedures, therefore the relative risks and benefits of laparoscopy should be considered on a case-by-case basis (SAGES, 2008).
The National Institute for Health and Care Excellence (NICE) guidance on obesity management in adults and children stated that bariatric surgery is recommended as a treatment option for people with obesity if all of the following criteria are fulfilled:

- the person has a BMI of 40 kg/m² or more, or between 35 kg/m² and 40 kg/m² and other significant disease (e.g., type 2 diabetes or high blood pressure) that could be improved if they lost weight
- all appropriate non-surgical measures have been tried but have failed to achieve or maintain adequate, clinically beneficial weight loss for at least six months
- the person has been receiving or will receive intensive management in a specialist obesity service
- the person is generally fit for anesthesia and surgery
- the person commits to the need for long-term follow-up

Bariatric surgery is also recommended as a first-line option instead of lifestyle interventions or drug treatment for adults with a BMI of more than 50 kg/m² in whom surgical intervention is considered appropriate (NICE, 2006).

The European Association for Endoscopic Surgery (EAES) issued evidence-based guidelines for obesity surgery in 2004. According to the EAES, adjustable gastric banding (AGB), vertical banded gastroplasty (VBG), Roux-en-Y gastric bypass (RYGB) and biliopancreatic diversion with duodenal switch (BPD/DS) are all effective in the treatment of morbid obesity. There is evidence that the laparoscopic approach is advantageous for LAGB, VBG, and RYGB. Preliminary data suggest that the laparoscopic approach may also be preferable for BPD/DS if surgical expertise is available, but further studies are needed. The report concluded that in terms of excess weight loss (EWL) percentages, BPD/DS is superior to RYGB which, in turn, yields greater EWL than VBG and AGB. However, the greater degree of EWL resulting from BPD/DS is at the expense of other outcomes (Sauerland, et al., 2005).

The American Association of Clinical Endocrinologists/American College of Endocrinology (AACE/ACE) states that all obese patients should undergo basic treatment which includes counseling, caloric restriction, behavior therapy, and physical activity. The goal of any basic treatment program is to integrate positive eating and physical activity behaviors into the patient’s life. The AACE/ACE recommends programs that actively encourage lifestyle changes and require participation in an ongoing, well-supervised weight-maintenance program. According to the AACE/ACE, surgical treatment of obesity may be considered only in carefully selected patients who are between 18 and 65 years of age with a very high medical risk (BMI >40 or BMI of 35 to 39 with life-threatening or disabling comorbid conditions such as diabetes mellitus, dyslipidemia, hypertension, or serious cardiopulmonary disorders). Suitable candidates should also have no history of alcoholism or a major psychiatric disorder and have a history of obesity for at least five years (AACE/ACE, 1998).

Use Outside of the US
Please see previous sections for relevant information from international organizations.

Summary
In general, surgical intervention is considered as a weight-loss option only after a comprehensive and sustained program of diet and exercise with or without pharmacologic measures has been unsuccessful over time. Certain bariatric surgical procedures have been shown to achieve significant weight loss, as well as to reverse or significantly improve obesity-related comorbidities in a carefully selected subset of morbidly/clinically severe obese individuals, when nonsurgical methods have failed.

Coding/Billing Information

Note: 1) This list of codes may not be all-inclusive.
       2) Deleted codes and codes which are not effective at the time the service is rendered may not be eligible for reimbursement

Covered when medically necessary:
